75. **Serotherapy of Cholera in Greece.**—Savas gives here minute details of the way in which cholera was stamped out in Greece last year. A previous account of it was published recently in The Journal, Aug. 22, 1914, p. 713.

76. **Vaccination Immunity to Small-Pox.**—Apolant relates that in a certain garrison with 120 men four had not been revaccinated since childhood. Two of these four developed small-pox and it was traced to an eating-house where there were two cases. All the men frequented the eating-house and

all had thus been exposed to contagion, but none contracted the disease except these two. The cases in the eating-house were in an infant that had not yet been vaccinated, and in the grandmother whose vaccination protection had evidently faded out. The child was saved from pitting in the face by compresses dipped in a weak solution of phenol.

77. **Phototherapy in Small-Pox.**—Würtzen insists that when small-pox patients are systematically and thoroughly sheltered against the chemical light rays—as in a Finsen red-light room or in a dark room—variola runs its entire course without suppuration, changing its character completely. He declares that wherever this has been done the finest results have been realized. He cites the literature on this subject of the red-light treatment of small-pox, including an article with this title in THE JOURNAL, July 17, 1909, p. 247.

79. **Therapeutic Inunctions with Green Soap.**—Külbs has applied green soap, with the same technic as for mercurial inunctions, in over 200 cases of various affections including nervous heart trouble, chronic bronchitis, emphysema, asthma, nervous dyspepsia and migraine—all affections in which revulsion is known to have a possible beneficial action on the local and general condition. There were no by-effects, no eczema or irritation of the skin while the benefit was surprising in some cases. It was most pronounced in the cardiac neuroses and migraine cases, but in the dyspepsia cases the appetite improved and the whole condition seemed materially benefited, as also in the respiratory affections. Asthma seemed less amenable; improvement was manifest only in three of ten cases. He gives a historical sketch of this method of treatment from Richter in 1846 to Hoffa's highly favorable report on 200 cases of tuberculous glands and Kausch's recent corroboratory report on its use in tuberculosis. He does not venture to explain the complex mechanism by which the favorable action is realized, but suggests that it may be analogous to that of air baths, sun baths and local hydrotherapeutic measures.

80 *Out-Door Air in Typhoid. G. Psarafti.

80. **Typhoid Mild Among Refugees.**—Psarafti discusses the peculiar mildness and absence of complications in a small epidemic of typhoid at Samothrace during the last Balkan War. The cases were all in refugees living in tents or other shelters during a rainy season, amid privations of all kinds, the people ignorant of hygiene and depressed by fear and want. Everything was exactly the opposite of what is usually deemed indispensable in treatment of a case of typhoid; even milk was not to be obtained. But the tents were not far from the sea coast and he ascribes to the pure air and sea breeze the exceptionally mild course of the disease, and insists that this experience should warn of the necessity for pure air for typhoid patients in particular.

92 Intravenous Injection of Concentrated Solutions of Neosalvarsan. J. van Assen.

85. **Thyroid Treatment of Dementia Praecox.**—Lemel remarks that when dementia praecox develops during puberty it seems self-evident that some disturbance in functioning of some organ or organs is responsible for it, and he is convinced that the thyroid gland can be incriminated in many cases and that the dementia may subside under thyroid treatment. This occurred in 11 of the 12 cases he here reports in detail. The improvement in 8 was most striking. Three of the patients were men from 17 to 24, the others girls of 19 to 21.

88. **Heliotherapy of Bone and Joint Tuberculosis at the Seashore.**—Andreae's experience with this at the Katwijk seaside sanitarium in Holland has been extremely favorable and free from deleterious by-effects.

91. **Intratracheal Insufflation.**—Van der Bergh and Wiersma know of very few instances in which the Meltzer and Auer method was applied in internal medicine, and they add another to the list. Their patient was a woman with a tumor in the cerebellum which evidently was injuring the respiration center as she gradually stopped breathing early one morning while in the hospital for consideration of operative treatment. As ordinary methods for artificial respiration were out of the question for permanent relief, and as at the end of an hour there seemed no hope of the woman's regaining spontaneously the power to breathe, intratracheal insufflation was applied, with prompt and striking benefit. It was kept up all day but toward evening the heart began to fail and the woman died at 7 p. m. This experience has demonstrated anew the advantages of intratracheal insufflation under certain conditions. No difficulty was experienced in this case in introducing the catheter into the larynx but if it should go astray in the esophagus the oxygen might injure the stomach lining. Others, including Meltzer, have warned of this danger.

100 *Action of Caisson-Work on the Blood. A. S. Solovtzova. Commenced in No. 13.

94. **Skin Tuberculin Reaction.**—Glinchikoff reports the results of extensive study of Pirquet's test in different diseases besides tuberculosis, pleurisy, pneumonia, typhoid, etc. Of the 40 tuberculous patients, 25 showed marked improvement of health, even recovery, and in these patients the skin reaction was intense. The Pirquet was very faint in the 10 progressive cases. In 5 stationary cases, the reaction was likewise stationary. The reaction is evidently in inverse proportion to the intensity and extent of the lesion in the lungs, and thus repeating the test at intervals may give an idea of the probable outcome in a given case. The same law proved to apply also in pleuritic patients, in typhoid, pneumonia, etc. In all acute infections the Pirquet was negative when the disease process was at its height and became pronounced with the recovery of the patient. Acute infections

give a stronger Pirquet than chronic disease, anemia, valvular heart lesions, disease of the liver, etc.

95. **Tubercle Bacilli in the Blood.**—Vinogradoff comes to the conclusion from examination of fifty tuberculous patients that the presence of virulent tubercle bacilli in the blood of patients with tuberculosis of the lungs or other organs is a phenomenon of rare occurrence and brief duration.

97. **Action of Poisons on the Vessels of the Liver.**—The frog or guinea-pig liver was isolated and flushed with Ringer-Locke's fluid passed through a pipet introduced into the abdominal vein (afferent) and posterior vena cava (efferent pipet). The portal vein, the hepatic artery and the common bile duct were ligated. Among the various chemicals tested, epinephrin, in a solution of 1 to 200,000 or 1,000,000 caused marked contraction of the hepatic vessels; beta-imidazolylethylamin (1:1,000,000) does not affect the vessels of the liver nor those of the periphery, but causes contraction of some vessels in guinea-pigs. Caffein (1:1,000) caused dilatation, as also pepton, while barium chlorid (1:1,000) did not act at all, or dilated the vessels in the frog, but in guinea-pigs it constricted them. Nicotin (1:1,000) induced contraction.

98. **Action of Poisons on the Vessels of Inflamed Tissues and of Epinephrin in Peritonitis.**—Eskin studied on the vessels of the normal or inflamed ears of rabbits the action of different substances including epinephrin, normal serum, serous effusion, caffein, cocain, and the toxins of cholera and of typhoid bacilli. Altogether forty-five experiments were made. He found that epinephrin acted on the vessels of an inflamed ear less than under normal conditions, frequently producing vascular dilatation. Caffein, normally dilating the vessels, causes a stronger vasodilatation in an inflamed ear. The reaction of epinephrin in artificially produced peritonitis is the same as in normal conditions, though it does not cause any marked constriction or any other action on the vessels of an inflamed mesentery or intestines. Serum (1:5,000) constricts normal vessels, but the action is less in case of inflammation. Cocain contracts the vessels of an inflamed ear less than those of a normal; weak caffein solutions (1:5,000 or 10,000) cause a stronger vasodilatation in an inflamed than in a normal ear. The toxins of different bacteria contract the vessels of both the inflamed and normal ear alike. Diluted exudates constrict the vessels of a normal ear, but do not influence an inflamed one.

99. **Diagnosis of Echinococcus Disease of the Liver.**—In two cases of alveolar echinococcus disease of the liver Serebriakoff did not find the usual clinical picture of this disease, namely, unusual hardness of the liver, regular enlargement and pain. To avoid blunders in diagnosis in such puzzling cases the blood should be examined for eosinophilia. It was pronounced in his two cases. Eosinophilia is due, in his opinion, to toxic influences produced by the echinococcus.

100. **Influence on the Blood of Working in Compressed Air.**—Solovtzova examined the blood of fifty-six caisson-workers. Their age was 20 to 40 years. Some were old, experienced caisson-workers, some were working in compressed air for the first time. The examination was usually six hours after the last meal. All of the men showed anemia in the form of decreased amount of hemoglobin and of the red corpuscles and frequently of the white. There was no parallelism between the low proportion of hemoglobin and of reds, as a considerable reduction in the hemoglobin percentage might be combined with a sudden increase in the number of erythrocytes. Microcytes would occasionally show; the polynuclear neutrophils showed a decrease, while the large lymphocytes and the eosinophils had increased. The reduction in the hemoglobin percentage and of the erythrocytes occurred with but an inconsiderable increase of the atmospheric pressure. In some of the men leukocytosis was evident. The blood returned to normal very slowly; even after an interval of two and a half weeks it was not always entirely normal. In those caisson-workers who had worked only two weeks, the blood became normal in a few days. As work in the caissons thus causes such serious blood changes, it is necessary to take all kinds of sanitary and hygienic precautions to guard the workingmen's health.

108 *Surgery of the Lungs. G. Ekehorn.

103. **To Close Gaps in the Skull.**—Löfberg reviews the different technics that have been applied for this purpose, including the use of a thin sheet cut from a cow's horn. This material was selected as being an epidermis substance which resists absorption unusually long although it in time is all absorbed. The regeneration of bone thus is able to keep pace with the absorption. Lindström and Lexer have had favorable experiences with horn, but Löfberg prefers an autoflap for the purpose. He reports excellent results in four cases of an extensive defect closed with a flap of periosteum and skin, taken from near by, or a strip from the internal lamina or with a sheet of bone and periosteum cut from the tibia. He mentions in conclusion Kleinschmidt's suggestion for a bone flap entirely covered with periosteum. This can be obtained by cutting with the bone flap enough extra periosteum to cover the other side of the bone.

104. **Severe Tuberculosis of the Bladder.**—Key says that the intensely painful subjective symptoms caused by the contraction of the bladder can be entirely arrested by diverting the course of the urine so that there will be nothing in the bladder to start it to contracting. The patient's life is not lengthened by the operation but he is spared torment by this exclusion of the bladder. The difference in the condition before and after was expressed by one patient as "the difference between hell and paradise." In the cases on record, the ureters were implanted in the bowel in 2 cases with the death of one patient. Permanent ureterostomy has been done in 3 cases with most gratifying results. Key contributes 2 cases to this group and extols the advantages of this technic. Nephrostomy was done in 6 cases, with one death. The drawback to nephrostomy is that it damages the kidney more or less. Ureterostomy is preferable if the ureters are still permeable.

108. **Surgery of the Lungs.**—Ekehorn's article is a discussion on the preferable method for regulating the atmospheric pressure during operations on the lungs; opinions are still divided as to the superior advantages of underpressure or overpressure.

111 Industrial Accident Insurance from Medical Standpoint. (Vor Ulykkesforsikringslovgivning og Lægerne.) V. L. Faber.

110. **Hematuria with Appendicitis.**—Nielsen has found records of 19 cases in which hematuria occurred apparently secondary to appendicitis, and in his own experience the microscope has shown blood corpuscles in the urine in a surprisingly large proportion of the cases. This occurred, namely, in 6 of 33 cases of chronic appendicitis and in 3 of 7 acute cases. The discovery of microscopic hematuria cannot be accepted, therefore, as an always reliable sign of a concrement in the kidney in dubious cases.

THE USE OF BOILED MILK IN INFANT-FEEDING*

ROGER H. DENNETT, M.D.
Adjunct Professor of Pediatrics in the New York Post-Graduate Medical School
NEW YORK

There are two distinct and entirely different reasons for boiling cow's milk during the first year of an infant's life: first, to destroy any harmful bacteria which the milk may contain, and by so doing to prevent disease; and second, to make the milk more digestible and to prevent or overcome any digestive disturbances, provided boiling has this effect. In this country the bacteriologic content of milk has attracted so much attention that we have not studied sufficiently the difference in the digestibility of boiled and unboiled milk, for we must study the problem entirely apart from the bacteriologic side.

All pediatrists are agreed that milk from healthy tuberculin-tested cows, and with a low bacterial content, is advisable for infant-feeding purposes. It is the general consensus of opinion in America that good milk need not be boiled, although some authorities are of the opinion that all milk fed to infants should be pasteurized. We are also agreed that when it is impossible to procure good milk, sickness can be avoided by pasteurization or boiling, and that one or the other is necessary when a good milk-supply is not available. The only question then, so far as the bacteriology of milk is concerned, is whether or not pasteurization or boiling of milk may be continued over a prolonged period without harmful results.

Perhaps an even more important phase of the question is whether the boiling of cow's milk so changes it that it is better borne by infants who have a low digestive capacity or who are suffering from actual digestive disturbances.

Our problem, then, divides itself into several subheads:

1. Does the prolonged use of boiled milk cause nutritional disorders, such as rickets, anemia, malnutrition, poor musculature or scurvy?
2. Does the change from unboiled to boiled milk cause digestive disturbances when fed to infants who have no difficulty in digesting unboiled milk?
3. Does the change from boiled milk to unboiled milk ever cause digestive disturbances?
4. Does boiled milk aid us in overcoming digestive disturbances such as intestinal indigestion with or without diarrhea or vomiting?
5. Does boiled milk cause constipation?
6. Is boiled milk as readily assimilated as unboiled milk, or is the nutritional value of milk lessened by boiling?

There are three ways of attacking these problems: first, laboratory experiments; second, animal experiments, and third, clinical observations on babies. There has been a great deal of work done and there is a vast amount of literature from the first and second points of view, but very little has been written on the clinical side of the question. Laboratory and animal experiments are very valuable, but the real test of any feeding problem is the actual results obtained in a series of babies who are carefully observed over a long period of time. Most of those who have written on this subject have concluded that actual clinical observations were necessary to determine the relative value and usefulness of boiled and unboiled milk in infant-feeding.

Some of the animal and test-tube experiments, although interesting and instructive, do not throw any real light on the practical problem of feeding. For instance, whether calves do as well on boiled cow's milk as they do on unboiled milk of their own species, and whether babies do as well on boiled human milk as unboiled milk of their own species cannot help us to decide the problems which I have enumerated above. At best the feeding of cow's milk to babies is an artificial procedure, and we must not allow such analogies to confuse us.

In approaching the subject from a clinical point of view, it is necessary that the babies on whom any feeding experiments are tried should have good care and the proper hygienic surroundings in order to be under the most favorable and natural circumstances. For this reason, it would be better not to take institution infants or those in the lower walks of life whose hygienic surroundings are poor. I have selected for my cases my own private patients and a few of the better class of dispensary patients whose intelligence can be relied on to carry out the directions ordered.

THE QUESTION OF NUTRITIONAL DISTURBANCE

1. Does the prolonged use of boiled milk cause nutritional disorders, such as rickets, anemia, malnutrition, poor musculature or scurvy? At the very start we must realize that in this question we are hampered by tradition. We have all been taught and have heard it repeated so many timse that boiled milk was liable to cause constitutional disturbances, that it is difficult to put oneself into the position in which his mind is open. Where this theory originated I do not know, but surely there is no conclusive evidence found in the literature to prove that boiled milk does cause these disturbances. Morse, in a very thorough review

---

* Read before the Section on Diseases of Children at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

precaution taken in the proper icing of the milk, care of the bottles, nipples, etc., in many instances by a trained nurse who is thoroughly familiar with the dangers of milk infection.

A very interesting experience occurred some years ago during my summer service in the babies' wards of the New York Post-Graduate Hospital, when I was first working with boiled milk. There were thirty cases of various kinds of gastro-enteritis that were being bottle fed in the wards. I had been rather blindly giving boiled milk as a routine for two weeks with varying success, during which time not a single one of the infants had any tough, hard curds in the stools. A sweeping order was given to stop boiling the milk and in almost every instance the curds appeared. In three days another sweeping order was given to boil all the milks, and in from twenty-four to thirty-six hours the stools of all the babies were free of curds. This experience has since been repeated so frequently in so many of my cases that there cannot be any doubt that changing from boiled to unboiled milk is a cause of digestive disturbances.

4. Does boiled milk aid us in overcoming digestive disturbances, such as intestinal indigestion with or without diarrhea, or vomiting? There are so many different factors that enter into the treatment of the various digestive disturbances that one must be careful when he attributes his success in treating a single case or a series of cases, to any single one of these factors, such as the boiling of the milk. The intervals between the feedings, the quantity at a feeding, the caloric value of the food, the amount and kind of sugar used, the addition of starches or dextrinized starches, the dilution, the percentages of fat and protein, the kind of milk used, the proper preparation of the food, and carrying out of the directions, all play an important part in overcoming digestive disturbances. It may be assumed that intestinal or gastric indigestion cannot be influenced by any procedure when the details are not properly carried out.

It has been my custom to begin the treatment of almost all of my cases of simple intestinal indigestion (and this does not include cases of infectious gastro-enteritis), with a mixture of about one-third milk and two-thirds water boiled as described above. No starch or sugar or alkali is added to the mixture. The simplicity of this procedure and the almost universal application of it eliminates many complicating problems, and since it is almost always successful in overcoming the digestive disturbances in the proper class of cases, it is fairly easy to determine what part the boiling of the milk plays in the success of the treatment. In other words if, in a certain class of babies, the universal use of one-third milk and two-thirds water boiled will overcome the digestive disturbances, it is only necessary to use the same mixture, unboiled, in a series of the same class of cases to determine whether the boiling of the milk is, in part at least, responsible for the good results obtained. It is very evident from my experience that many cases of intestinal indigestion cannot be successfully treated with this mixture unboiled.

The following case, picked out at random, is typical of the series of cases which were treated with boiled-milk mixtures:

A. P., boy aged 4 months 2 weeks. Birth weight 9 pounds 8 ounces. Present weight 10 pounds 8 ounces. Temperature 98.6. Skin rough, very poorly nourished, milk malnutrition, good bony development. Previous food, 7 per cent. top milk, 13 ounces; water, 19 ounces; lactose, 7 teaspoonfuls; 4 ounces every three hours; seven feedings in twenty-four hours. Stools: Six or seven in twenty-four hours, green, watery, with mucus and curds. Appetite: Hungry. Sleep: Poor. Vomiting: None.

Treatment: Milk, 10 ounces boiled; water, 20 ounces boiled; no sugar; 4 ounces every three hours; seven feedings in twenty-four hours.

In three days there were two yellow, soft, homogeneous stools without mucus or curds, which remained normal thereafter, when the milk was increased and sugar added.

In fifty-two cases treated with this boiled-milk mixture the stools became normal in from two to five days. The ages varied from 3 weeks to 1 year. The stools varied from three to twenty per day, all of them showing evidences of indigestion and most of them containing mucus and curds. As many of these cases were treated in summer as in winter. The weights varied from 4 pounds 5 ounces to 19 pounds 4 ounces, the majority of them being small, emaciated, young infants. The previous feeding varied from simple barley gruel, which in some cases had been used for a prolonged period without overcoming the diarrhea, to the more complicated top milk and whey mixtures and the various proprietary foods. There were all grades of intestinal indigestion, but no acute infectious diarrheas are included in the group, as it would seem as though such cases have too many complicating elements to be of any value in deciding whether boiled milk is more easily digested than unboiled milk. However, it may be said in passing, if boiled milk is more easily digested than unboiled milk it would naturally follow that cases of acute infectious diarrhea which require milk feeding should receive the milk boiled.

The series of cases in which the unboiled milk was used in the same dilution is small, because of the poor results obtained, as it did not seem fair to the infants to allow them to continue with the unboiled milk since the stools did not improve under this treatment. A typical case treated with the unboiled milk is as follows:

L. L., girl aged 4 months. Weight, 9 pounds 14 ounces. Temperature, 98.6. Skin, smooth. Poorly nourished, good bony development. Previous food: Ten per cent. top milk, 5 ounces; water, 20 ounces; lime-water, 2 teaspoonfuls; milk-sugar, 4 teaspoonfuls. Stools: Three, loose, watery, with much mucus and curds. Vomiting: A great deal at every feeding. Appetite: Ravenous. Sleep: Poor.

Treatment: Milk, 10 ounces, unboiled; water, 20 ounces, unboiled; no sugar; 4 ounces every three hours; seven feedings in twenty-four hours.

At the end of a week the stools were not only not improved but were more numerous, and large, tough curds took the place of the soft, fatty ones. The food was then boiled and in three days more the stools became smooth, homogeneous, free of curds and mucus.

There were ten cases in this series which included the same kind of babies as in the boiled-milk series. In only two did the stools clear up without resorting to the boiled milk, and those were infants that had formerly been receiving extremely bad feeding, one a very high fat and the other very high sugar. In the other eight the diarrhea was allowed to go on for seven days in three cases, nine days in three cases, and twelve days in two cases, before the boiled-milk feedings were instituted. In all of these cases the stools became normal inside of five days after beginning the boiled milk.

These boiled-milk mixtures are particularly useful in the small, young, poorly nourished infants, who do not do well on an exclusive carbohydrate diet, such as is so frequently given for a few days before starting milk feedings. It is probably the experience of all of us that the older, well-nourished infants, say above 6 months of age, who have *intestinal indigestion*, are best treated with either an entire cessation of food for from twelve to twenty-four hours, or a starch diet such as the various gruels and perhaps bread pap. But the younger, smaller infants and those with malnutrition who are suffering from the lack of food do not do well with this treatment. It is not an uncommon experience to see infants of this class that have been fed barley-gruel for a period of a week or more with no improvement in the stools and with a marked loss in weight and strength.

It is not easy to determine the effect of boiled milk on the gastric digestion. Often severe vomiting was stopped or the severity much diminished when boiled-milk mixtures were given in simple dilutions. However, this generally occurred in infants who came under observation for the first time, and whose feeding had previously been more or less irrational. Besides that, the sugar is usually cut down in amount and many other proper changes are made. On the other hand, there are certain infants whose vomiting does not stop with the boiling of the milk.

I have certainly never seen vomiting caused by the change from unboiled to boiled milk, nor am I sure that I have seen it caused by the change from boiled to unboiled milk. Undoubtedly the large, tough curds that are seen in the stools of some infants fed with unboiled milk are originally formed in the stomach, and unboiled milk stays in the stomach longer than boiled milk, both of which facts Brennemann has shown.

CONSTIPATION

5. Does boiled milk cause constipation? Constipation in the bottle-fed has so many different causes that it is difficult to prove what part the boiling of the milk plays in its etiology. In many of my patients who were constipated when the boiled milks were started, the constipation was overcome during the period that the boiled milk was fed. In others the constipation persisted while on boiled milk but was relieved when unboiled milk was given. Still others who were constipated on the boiled milk feeding were just as constipated after the feeding was changed to unboiled milk. None of the babies that received the malt-soup mixtures were constipated at any time while taking this food, which shows that even if constipation is caused by boiled milk and water mixtures, adding certain elements to the food will overcome the constipation in spite of the boiling. Infants who have diarrhea at the time that boiled milk is instituted often acquire a much welcomed constipation. The constipation is then usually overcome as sugar is added to the food, and the food is increased in quantity and strength.

Of the thirty-one babies that were constipated at some time while they were receiving boiled milk as a food, in nineteen the constipation was overcome before the food was changed to unboiled milk, in six the constipation was relieved by stopping the boiling and in six others the constipation persisted in spite of the change from boiled to unboiled milk.

It would seem that although constipation more frequently occurs in babies fed on boiled milk, in certain cases it may be overcome while the baby is fed on boiled milk, and stopping the boiling does not always stop the constipation.

NUTRITIONAL VALUE

6. Is boiled milk as readily assimilated as unboiled milk, or is the nutritional value of milk lessened by boiling? This is a phase of the question that cannot be decided by clinical work. There is a certain loss of fat and protein when a scum is allowed to form on top, but if the milk is stirred constantly and brought to a boil rapidly this scum is not formed. It is my opinion that even when this detail is carried out, there is a small loss in the nutritional value of the milk. My only evidence, which *is not at all conclusive*, is based on the increase in infants' weight on stated amounts of boiled and unboiled milk.

CONCLUSIONS

1. Clinical evidence of the comparative usefulness of boiled and unboiled milk in infant-feeding is of value and desirable.
2. The prolonged use of boiled milk if properly administered does not necessarily cause nutritional disorders such as rickets, anemia, malnutrition or poor musculature.
3. Scurvy may be avoided when boiled-milk feedings are given, by the administration of orange juice.
4. Boiled milk does not cause digestive disturbances in normal infants, and is, therefore, not more difficult to digest than unboiled milk.
5. Boiled milk aids us in overcoming digestive disturbances.
6. The change from boiled milk to unboiled milk may or may not cause digestive disturbances.
7. Boiled milk is probably more apt to cause constipation than unboiled milk, but in certain cases the constipation may be overcome while on boiled milk, although it is not always overcome when the boiling is stopped.
8. The evidence is not conclusive whether the value of the milk is lessened by boiling or not.

ABSTRACT OF DISCUSSION

Dr. Frank C. Neff, Kansas City: I think if one looks over his case-records of scurvy he will find it more or less difficult to determine just what sort of feeding has been responsible for this. I was interested in the report of Dr. Brennemann in which he stated that recovery ensued in a well-developed case of scurvy from the use of boiled milk; there was no other food and no other medication and it cleared up as quickly as scurvy often clears up under the administration of fruits. I have also seen cases of scurvy develop during the *administration of raw milk*. Such a case I saw last year. One is inclined to doubt that a moderate heating of milk has any relation to the production of scurvy.

Dr. L. T. Royster, Norfolk, Va.: I give percentage feedings as a routine, using cream, skimmed milk, water and carbohydrates. I also believe in using home modification when possible. We have in Norfolk good certified milk, also a laboratory. I have also a number of patients coming from the surrounding country for many miles, who cannot get either laboratory milk or certified milk, and in those cases I use home modification. The milk-supply being so doubtful, I never hesitate to boil the milk and have never seen any deleterious results therefrom. As a rule I use orange juice in those cases; but sometimes do not, and have never seen any bad symptoms, even in cases in which the orange juice was not used. I saw some of Dr. Leopold's cases last summer and followed them with much interest, and, having a number of institution patients myself, tried the treatment on them on my return. I got good results in the majority of cases. Some of them, especially when there was bad nutrition to start with, did not show as good results as a fairly normal child on normal feeding. Referring to the oft-discussed question of institution babies, one of the main reasons why institution babies do not do well is that they do not get as much individual care as a home baby. I believe whenever you go beyond four babies to a nurse in an institution you are on the ragged edge, and the further you get away from that, the poorer will the results be. In my own experience, when I have one nurse to four babies, I practically never have a case of institutionalism develop. I also believe that harm from boiled milk has been much overrated.

Dr. H. Lowenburg, Philadelphia: I have been using boiled milk for the last three years, usually in combination with flour, or old-fashioned flour-ball. My results have been according to Dr. Dennett's observations that it has an excellent effect on the stools, immediately causing disappearance of the curds, and change in color to golden yellow. My attention was called to an article in The Journal, Feb. 22, 1913, p. 575, by Brennemann, who did a lot of experimental work showing the effect of coagulants on the curd of boiled milk, and indicated clearly that these curds resembled human milk more than the unboiled milk. The possibility of scurvy has always interested me also. Every time I get a case of [illegible]urvy I cure the patient with raw milk, and I have never [illegible]l a case of scurvy develop in my own work. That is [illegible]obably due to the fact that all the children get beef broth and vegetable broth. I never use orange juice.

Dr. Charles Douglas, Detroit: As to boiled or pasteurized milk, from twelve to fifteen years ago I was a very strong advocate of raw milk. I talked it among my patients and used it, and I found, after doing so for a few years, that my results from boiled milk were much better. I would not think of going back to raw milk. Scurvy is so easily cured that I do not think it is worth talking about. If I see any suspicious symptoms I put in a little orange juice and get rid of scurvy in that way. With regard to the curds in raw milk, if the amount of raw milk is reduced 1 or 2 ounces in the day's feeding, the curds will disappear. The change to boiled or pasteurized milk impressed me that a child could not digest as much raw as boiled or pasteurized milk, as curds did not appear when the latter was given.

Dr. George Dow Scott, New York: I believe milk is changed through boiling. It seems to me that when the cow gives a natural food, boiling it is not only unnecessary but harmful. When we get a physiologic food from the cow it is only necessary for us to modify it in the raw state sufficiently so the child can take it. I see advantage over the old wine-whey, in Schloss' mixture. If raw milk is modified with the proper amount of fat protein and carbohydrate, the child will progress. The question of scurvy is always brought forward. Recently I read an article in New York quoting over 100 different authors on scurvy. I had to wake my audience up every little while because it was going to sleep listening to my numerous quotations. I think scurvy comes from a poor condition of the milk due to delay in handling and in getting it from the dairy to the consumer. That certainly has much to do with it. I do not agree with Dr. Douglas that scurvy can be cured in a few days. I think it is a long-drawn-out condition, and takes prolonged treatment to cure.

Dr. G. W. Graves, New York: I have seen no less than four severe cases of scurvy develop under boiled-milk feeding, in the hands of perfectly competent practitioners, and know that the condition has been most serious in the eyes of the families. The children have been quite ill and have suffered excruciating pain; and the anemia has been very marked. When boiled milk cannot be found to be the cause in such cases, pasteurized milk may be. ("Raw" milk is a term very frequently applied to pasteurized milk.) Boiled milk has a distinct value, but when cooked milk is used, it cannot be emphasized too strongly that orange juice, potato water, or some other antiscorbutic should be employed.

Dr. J. L. Morse, Boston: It does seem a great pity to speak of any rule or method of infant-feeding. There are just two reasons for boiling milk—one is that bacteria are in the milk, the other is that there is a disturbance of the casein digestion. We know that boiling the milk will kill bacteria and that it makes the digestion of casein easier. When we have casein indigestion, boiling is one way to correct it. I would rather feed babies continuously on raw milk than on boiled milk. As to whether boiled milk causes scurvy, the only statement we can make regarding the etiology of scurvy is that no one knows anything about it. We all have certain ideas. I have found that, during the last few years, the condition which has been more constantly present than any other in the feeding of the babies which I have seen with scurvy, is that the milk has been heated in some way. Yet I feed babies on both boiled and raw milk.

Dr. Roger H. Dennett, New York: I do not agree with Dr. Morse's last statement. I do not believe that, after an extensive use of boiled milk, anybody can possibly say the boiling of milk has no effect except in destroying bacteria and in overcoming protein indigestion. I have seen, for instance, an infant that has had a prolonged diarrhea treated perhaps for a week or two with barley gruel, which we all agree is a mistake. Inside of three days after feeding this child boiled-milk mixture the stools were back to normal for the first time. This infant was having three, four and up to seven loose, mucous stools a day, and inside of three days of the boiled-milk feeding, the stools became normal. This is not protein indigestion. As I have shown in my paper, the same results cannot be obtained with the same feedings when the milk is given raw. Babies will stand a higher protein better when the milk is boiled.

FRAGILITAS OSSIUM*

MAURICE OSTHEIMER, M.D.
Associate in Pediatrics, University of Pennsylvania
PHILADELPHIA

In 1897 Dr. Griffith[1] was able to collect sixty-seven cases of "idiopathic osteopsathyrosis" in infancy and childhood. He included under this head all cases of multiple fractures occurring before birth, at birth and after birth, in which no cause for the bone fragility could be found. The German writers still use the term "osteogenesis imperfecta" for the cases found at birth, while the French call them *"dysplasie periostale;"* and both reserve "idiopathic osteopsathyrosis" for the condition of multiple fractures, of an unknown cause, occurring later in infancy and childhood. There can be little doubt now that these two conditions are identical, being but different stages of the same disease, as is shown by Axhausen,[2] Bamberg,[3] Frangenheim,[4] Hagenbach,[5] Hammond,[6] Hartmann,[7] Lipschütz,[8] Looser,[9] Matsuoka,[10] Porak and Durante,[11] M. B.

Schmidt,[12] Schuchardt,[13] Sumita,[14] Ziegler[15] and others. The name originally given to this condition, together with "achondroplasia" ("chondrodystrophy foetalis"), was "congenital or fetal rickets." At that time "achondroplasia" had not yet been differentiated from "osteogenesis imperfecta." Birnbaum[16] noted but one case of "osteogenesis imperfecta" among 4,500 births in the Göttingen clinic, showing how very rare the condition is. Vrolik[17] first used the name "osteogenesis imperfecta;" Lobstein[18] called it "osteopsathyrosis"; Kundrat[19] called it "osteoporosis congenita"; Marchand[20] called it "osteomalacia congenita;" Klebs[21] and Hochsinger[22] used the term "fragilitas ossium." We prefer "fragilitas ossium" since it accentuates the chief clinical symptom of the disease.

We have used the term "fragilitas ossium" to include both types of cases, (1) the fetal type found either at birth or soon afterward, associated with imperfect bone formation and multiple fractures (imperfect osteogenesis or periosteal dysplasia), these cases commonly not surviving beyond the second year of life; and (2) the congenital type, found in infants and children, at birth or later, with fractures recurring often until puberty or even until adult life, associated with similar bone changes (idiopathic osteopsathyrosis), which children if well cared for, survive, but often in a badly crippled condition. Our extensive review of the literature has brought to light 126 cases since 1897. Like Dr. Griffith, we have rigorously excluded symptomatic cases (with three fractures or less) for which any cause could be discovered, such as secondary absorption due to rickets, osteomalacia, scurvy, or old age; osteomyelitis or tuberculosis of bones; syphilis, nervous affections, tumors, cysts, etc.

We report the following case from Dr. Griffith's service at the University Hospital. For permission to make this report we are indebted to Dr. Griffith; for the case-history, to Dr. M. B. Magoffin.

CASE REPORT

History.—A girl, 3 years old, of Russian-Jewish parentage, was admitted March 25, 1913. She was breast-fed up to one year; since then she has been carefully fed. She never had much indigestion. There are three other children, living and well. There is no history of fracture on either side. Her only illness was whooping-cough during the winter of 1912-13. Her mother states that "she breaks her leg almost every time she tries to stand up." At 1½ years she broke her left femur; at 22 months, right femur; at 2 years, left femur; at 26 months, left femur; at 28 months, right femur; at 31 months, left femur, and on March 21, 1913, at 3 years, she fractured her left humerus. She had bumped into a door gently.

Physical Examination.—She is quite intelligent, noting everything about her, and very much spoiled. Though undersized, she is fairly well nourished; skin is warm and moist; musculature is good, except in legs. Head and face are broad, showing marked protruberance of the parietal bones, just above and in front of the ears. Both sclera are deep blue in color. Her ears, nose and mouth are apparently normal. There is no craniotabes. Her neck is short. The posterior cervical glands on the left side are markedly enlarged and hard. Thorax is pigeon-breasted, with prominent sternum. Expansion is good; both sides equal. The lungs are normal both to percussion and auscultation. The heart dulness extends from just outside the right edge of the sternum to the left midclavicular line and upward to the third rib. The apex beat, which is not visible, is palpable in the fifth interspace, in the midclavicular line. A soft blowing systolic murmur is audible; the second sound at the pulmonary area is accentuated. The rhythm is rather irregular and occasionally a beat is omitted. Her pulse is small, of moderate tension. The liver is palpable just below the costal margin. The spleen is not palpable. The inguinal glands are somewhat enlarged and hard, on both sides. There is considerable forward bowing of both femora, the evident result of the many fractures. Her left humerus is in plaster. Knee-jerks are normal on both sides. Examination of the blood showed erythrocytes 4,550,000, and leukocytes 10,200, with 48 per cent. polymorphonuclears, 1 per cent. mononuclears, 48 per cent. lymphocytes, and 3 per cent. eosinophils. Both von Pirquet and Wassermann reactions were negative.

Measurements, made with a pelvimeter (April 4, 1913), compared with those of a normal child then in the ward, were:

	Our Case cm.	Normal Child cm.
Biparietal diameter	14¾	14
In front of ears (4 cm. below that above)	15¼	12
Occipitofrontal diameter	16½	17½
Nasal to base of occiput	12	13½
Between malars	10½	11
Root of nose to top of chin (mouth closed)	9	9

The measurements with a tape-line were:	Inches	Inches
Circumference of head at parietal eminence	19⅞	20¼
Occipital protruberance to base of nose	12⅛	12⅝
Neck	8⅞	9½
Circumference just above ears	18⅞	19¼
Half-circumference just above ears (posterior)	9½	9⅝
Half-circumference just above ears (anterior)	9⅜	9⅝

Before a Roentgen-ray picture was taken she developed gonorrheal vulvovaginitis and was immediately sent to the Philadelphia General Hospital. Diligent search again led to her discovery six weeks ago, the family having moved three times. She is now even more spoiled than last year, and has broken each femur once in the past year, the left when 41 months old, the right at 45 months. She recovered rapidly each time and now manages to walk about a little, by holding on to chairs, etc. The family are constantly expecting her to break her legs again. There is more bowing of the femor and slight atrophy of the muscles of the legs. Her parents refuse to allow her to be removed to the hospital even for a Roentgen-ray photograph; in fact they refuse to allow her to be touched, she is so afraid of doctors. She looks quite anemic. To resume: Between the ages of 1½ and 4 years she has had nine fractures, breaking her left femur five times, right femur three times and left humerus once.

Dr. Griffith has also kindly given us notes of another case, which occurred in his private practice (1905-1906). This case appears in the table as No. 43. We have tabulated from the literature 124 cases, in addition to the 67 cases collected by Dr. Griffith in 1897, making 193 cases altogether. Besides, we learn that Dr. Walz showed a patient at the meeting of the Aerztlicher Verein, Stuttgart, on October 10, 1912,[23] but we have been unable to find any details of this case. Nor was it possible to procure a copy of the dissertation of Fridericia Gräfin von Geldern-Egmond (Zurich, 1897), in which another case is recorded.

It will be noted that in eleven of these cases, how long the infant lived was not known at the time the case was reported. The age at death was recorded in twenty-four cases, the oldest having reached 22 months.

The sex of the 117 infants born alive was noted as male in 62 (53 per cent.); female in 37 (31 per cent.); not mentioned in 18. The first fracture occurred between birth and 3 years in 64 (73 per cent.); from 4 to 11 years in 11 (13.5 per cent.); while the last fracture occurred under 13 years in 34 (42 per cent.); between 13 and 21 years in 28 (34.5 per cent.); between 22 and 41 years in 5 (6 per cent.). In seven cases the time of the first fracture, in 15 the time of the last fracture was not mentioned. The latest fracture recorded occurred at the age of 41 years. The bones of the legs, especially the femora, were most frequently broken. In number the fractures varied from 4 to 106. The cause of the fractures was usually trivial, without force or injury.

In only eight cases (9.8 per cent.) was the condition known to have existed in either parent; while brothers or sisters suffered from fractures in 24 cases, (29.6 per cent.). Although Frangenheim[115] states that the majority of these infants are born dead or die soon after birth, our tables show 82 patients living (65 per cent.), 33 cases dead (26 per cent.), with the result unknown in 11 cases (9 per cent.). In 43 cases (52.5 per cent.) the condition was noted as decidedly crippled; in 32 (39 per cent.) the patients were not disabled, while in 7 cases they were too young to record any result. In six of these 32 patients the presence of dark blue sclera was noted. The association of dark blue sclera with brittle bones, as was observed in our case, has been commented on by Stephenson,[116] Harman,[117] Burrows,[118] Rolleston,[119] Conlon[120] and Cockayne[121].

BONE CHANGES

The best description of the bone changes is given by Nichols.[122] "There is evident lack of formative power in the bone tissues. Instead of new bone being formed by normal osteoblasts on a cartilaginous matrix, the bone trabeculae are produced by calcification of the cartilage cells. Both layers of the periosteum are thickened, forming non-laminated or imperfectly laminated dense bone, with no Haversian canals, but large marrow spaces, in which there are few trabeculae. The marrow is abnormal, containing much connective tissue. The trabeculae are studded with flattened osteoblasts, but there is no evidence of osteoid tissue. The process of bone formation is checked and abnormal. Metaplasia of cartilage is much greater than normal, while bone deposition is much less. The formation of periosteal bone is abnormal and incomplete." Frangenheim[4 and 115] also notes the imperfect bone production, with increased absorption of the scanty bone trabeculae. The bone productibility of the periosteum is distinctly inhibited. That there is sparse bone proliferation with increased absorption of bone substance is mentioned by Scheib,[11] Helwig[17] and Harbitz.[51] Harbitz[51] notes that the bones contain much less calcium salts than normal. Maier[88] also noted the lack of calcium salts and the "concentric bone atrophy." He calls attention to the fact that while the long bones are bowed, there is no real shortening; they are much thinner and their structure is changed. Nathan[76] lays stress on the bowing of the long bones which are not truly shortened. M. B. Schmidt[12] believes that there is normal or somewhat delayed proliferation in the cartilage, with scanty bone production on the part of both marrow and periosteum; as a result, the bones are thin, porous and very fragile. Very few osteoblasts can be found in any part of the skeleton.

Ziegler[15] states that the marrow cavity enlarges and the bone becomes porous and fragile. Thus fractures result readily. Doering[107] and Rebbeling[66] believe that the productibility of the periosteum is increased and that dysplasia occurs through abnormal absorption on the periosteal surface of the bone. The marked atrophy in the thickness of the diaphyses which results, is commented on by Schuchardt,[13] Rebbeling,[66] O. Schmidt,[65] Looser[9] and Kaufmann.[123] Lange[91] believes the fragility to be due to the fact that while normal absorption goes on inside the compact substance, no periosteal layers are laid down outside, so that the cortical layer becomes thin, bends and finally fractures. Sumita[13] describes a functional inability of the periosteal osteoblasts, with normal enchondral preparatory processes. Michel[28] found such marked diminution in periosteal bone formation that the bones were merely shells of calcified bone spicules. Goldthwait, Painter and Osgood[124] note that the process of bone formation is everywhere checked and abnormal. Klotz[37] states that the faulty bone production is the result of imperfect metaplasia of the perichondrium into periosteum. He considers this due to lack of stimulus, or to some inhibiting force acting on the osteogenetic tissues. Hildebrandt[40] believes that some injurious substance circulating in the blood prevents the absorption of cartilage and the formation of bone substance.

The fractures, which occur in the diaphyses only (Maier[88]) depend on structural changes in the bone (von Recklinghausen[64]). Kardamatis[59] believes that these changes in the structural relations must explain the spontaniety of the fractures of the bone substance. Lindemann[44] considers the primary affection to be of the marrow, with secondary changes in the periosteum. He found small cell infiltrations most marked in the marrow cavity and blames these for the occurrence of the fractures. Frangenheim[4 and 115] also believes that the cause probably lies in the abnormal marrow, which is not able to produce normal functioning osteoblasts.

The only blood count which was unusual was reported by Maier,[88] giving an increase of eosinophil leukocytes up to 14 per cent. In our case the eosinophils were only 3 per cent.

The diagnosis is not difficult in cases of the imperfect osteogenesis type. There is a premature or full term fetus, either born dead or living less than two years, showing more or less imperfect cranial ossification (sometimes with a membranous cranium), apparently shortened, bowed extremities and multiple fractures, both old and recent. In cases of the idiopathic

osteopsathyrosis type, the diagnosis is no more difficult, for multiple recurring fractures in infants and children, without explainable cause, could be due to nothing else.

The relationship between fragilitas ossium and achondroplasia is certainly close. According to Jansen[125] the short extremities in both conditions are due to compressibility of the scleroblastema by enhanced amnionic pressure and to vulnerability of the fast-growing cell groups. He believes that a small amnion must be formed in these cases. Cases of the imperfect osteogenesis type may resemble achondroplasia: in both instances the extremities appear shortened, the long bones bowed or curved, and the facial expression seems similar. But as Dieterle[38] notes, the primary changes in achondroplasia are in the cartilage, while in fragilitas ossium there is a functional disturbance of both periosteum and endosteum. Zurhelle[33] states that achondroplasia shows scanty growth of the cartilage cells and early cessation of enchondral ossification, while in fragilitas ossium there is functional inability of the periosteal osteoblasts, with resulting scanty bone production and normal or almost normal enchondral ossification. Hochsinger[126] explains that in achondroplasia the short limbs come from limitation of linear growth in the long bones; in fragilitas ossium from multiple fractures and bending of the shafts of the long bones as the result of a faulty process of ossification. Hartmann[7] calls attention to the value of the Roentgen ray in diagnosis, since it demonstrates the marked disappearance of bone substance in the lower extremities. Mourad[49] believes that the epiphyseal lines in the Roentgen-ray photographs make the diagnosis between fragilitas ossium and achondroplasia certain. This imperfect bone formation and the multiple fractures readily separate fragilitas ossium from achondroplasia.

Rickets and osteomalacia must also be differentiated from fragilitas ossium. Besides the bone changes, if fractures occur, they are few (less than three or four), and they occur with some injury. Rachitic changes have been noted during infancy in several of the cases of fragilitas ossium reported; but Roentgen ray and histological examinations later have excluded rickets. Hochsinger[22] reiterates the fact that fractures are rare in rachitis. Wieland[127] asserts the now general belief that there is no such condition as congenital rickets; while Escher,[128] in exhaustive investigations, was unable to find anything to make the diagnosis of congenital or fetal rachitis tenable. Reyher[129] considers it important not to let any case of rickets be included among the cases of fragilitas ossium.

Though cases of so-called "juvenile osteomalacia" have been reported by Axhausen,[2] Rees[37] and Anschütz,[93] careful observers have classified their cases as either fragilitas ossium or true rickets. Looser[9] called some of them cases of late rickets. But he is certain that no general disturbance of nutrition can cause fragilitas ossium. Scholz[89] thinks that it would look as though the cases of "juvenile osteomalacia" and fragilitas ossium were but different forms or stages of the same process. Schuchardt[13] defines osteomalacia as a lack of calcium in the finished bone, which is limited in its growth. The effects of softening are noted only in the diaphyses, which fact distinctly separates osteomalacia from rachitis. And the occurrence of few fractures, only rarely, and with serious injury, separates both rickets and osteomalacia from fragilitas ossium. Klose[90] says that "even if rickets or osteomalacia be considered the cause of fragilitas ossium, the question of the etiology of the high-grade fragility is not solved. Repeated fractures do not belong to either rickets or osteomalacia and we must see a special pathogenesis, etiology and anatomy in cases in which multiple fractures occur."

PROGNOSIS

The prognosis is usually unfavorable. In spite of the best care fractures recur without much cause and over one-half of all patients remain badly crippled as a result. In 76.5 per cent. of our cases the last fracture occurred under 22 years of age, yet our records show fractures as late as 33, 38 and 41 years. While in 39 per cent. of our cases the result is given as fair, it should not be forgotten that reports of later conditions in these patients are not available; were they recorded, more badly crippled cases would undoubtedly be added to the list.

TREATMENT

The treatment, outside of the local treatment for each fracture as it occurs, consists in attempting to prevent the recurrence of fractures. When infants, these children are carefully guarded on mattresses, and they are hardly permitted to move. Fresh air, careful hygiene and good food are of importance. Cod liver oil, phosphorus and calcium salts have all been given, but without much result. As the etiology remains undiscovered, no beneficial method of treatment has as yet been found. Undoubtedly the condition is congenital; it would seem probable, therefore, that some fault of metabolism in the pregnant woman is the cause of fragilitas ossium in her offspring.

ABSTRACT OF DISCUSSION

Dr. E. A. Park, Baltimore: Will Dr. Ostheimer state why the name "osteogenesis imperfecta" would not be more appropriate than fragilitas ossium? Apparently the process is a specific one. There is a general activity of the osteoblasts throughout the bones, both at the junction of the cartilage and bone and in periosteal ossification. It seems to me osteogenesis imperfecta would be more proper. There is nothing in the term "fragilitas ossium" which implies a specific process. In the multiple fractures in rachitic bones, for instance, certainly a condition of fragilitas ossium obtains, but the picture in that condition is distinctly different from that which Dr. Ostheimer has described.

Pedagogy Among the Chronic Insane.—E. F. Leonard, in the *Institution Quarterly* for September 30, reports an experience incident to his service on the staff of the Jacksonville (Ill.) State Hospital. An unusually obstinate patient was by degrees drawn out to take an interest in magazines and was one day found surrounded by a group of patients to whom he was reading and explaining an article. The reading circle grew and the hitherto morose patient's condition improved. He was persuaded to start a school among the other patients of his ward. The school was taken seriously by teacher and pupils (all patients); a library was instituted, a singing school and Sunday school started, and the ward, which had previously been somewhat violent and hard to interest even in a daily newspaper, gradually improved. The work was in progress for about four years, during all of which time the interest was sustained. The teacher patient was finally discharged from the hospital as recovered and is now earning a living for his family.

PREVENTIVE OTOLARYNGOLOGY*

BURT R. SHURLY, M.D.
DETROIT

We are suffering mentally, physically and financially from too many medical societies, too many new instruments and accessories and too many surgical operations with the name of the surgeon as the distinguishing pennant of the operation. It will soon be time to appoint a board of censors centrally located to which instruments and operations may be presented and which will approve those worthy of attention before the profession and public are subjected to so-called improvements.

The practitioner and specialist of this country is particularly distinguished for a keen uplifting interest in humanity, a broad sympathy and a devotion to the greater comfort and general welfare of the patient. It is still true, however, that the most noble and skilled exponent of our special art must pay homage and reverence to the greatest queen of all—Dame Nature; her ways of prevention, medication and cure must be ours.

The mind of the medical man in the last two decades has originated, elaborated, improvised and invented innumerable systems, methods and instruments to eliminate pathologic or other tissue from the nose, throat or ear, yet the pages of our literature on preventive methods of procedure in our specialty have been few indeed. The question of when not to operate may be uninteresting, but as a valuable consideration in the saving of life it is frequently as important in otolaryngology as in the surgery of the appendix.

It is unnecessary for us to follow the Mohammedan custom of daily chant, and open our office each day with a recital of the Hippocratic oath and ten laws of Dame Nature which must be obeyed, but it is fitting and proper that we should frequently ponder on the great and serious responsibilities of our calling. This applies especially to our overzealous radical colleagues who seem to consider surgery the only road to success. It takes a conscience, introspection, sympathy and a true sense of responsibility to realize that the limitations of one's individual surgical ability and training must be the guiding stars of decision and judgment. The value of any instrument, operation or method depends on proper selection and use.

Are we to ligate the carotid for tonsillar hemorrhage? Yes, if necessary; but if a brilliant and dexterous general surgeon is in an adjoining operating-room he should be called in as he can accomplish the work skilfully in half the time it would take a laryngologist. The old adage "An ounce of prevention is worth a pound of cure" applies to otolaryngology and may be resuscitated at this time with advantage. Prophylaxis is the text of the dentist as he merrily bores into the decayed tooth. We hear the pathologist assert that immunity and heredity explain the problem. Eugenics will reform the world, says the pediatrist. Sanitary science, hygiene and quarantine are the interesting themes of the internist.

The subject of preventive otolaryngology may be classified to include a system of observances that will offer the best protection or prevention to the individual or community of diseases of the nose, throat or ear.

Preventive medicine will not be appreciated by the laity or profession until a secretary of public health in the cabinet at Washington shall organize, develop and promote this subject with its special branches for the benefit of humanity.

The practical importance of the prevention of disease in the upper respiratory tract and the accessory channels of the ear grows on one as it is viewed from the biologic, sociologic, pathologic, or therapeutic point of view. Under the subclassification of protective otolaryngology it is possible to accomplish much of great practical value to the community at large.

Your Chairman of 1910, Dr. Jackson, has called attention to the necessity for compulsory labeling of poisons sold by grocers. There are many preparations of caustic alkali that have been accidentally taken by children, and many hundred cases of cicatricial esophagial stenosis must have occurred through laxity in making and enforcing laws regulating the sale of poisons. Our delegate should be instructed to investigate this matter and present another resolution on this subject to the House of Delegates if necessary.

The problem of noise and its deleterious effects on the auditory nerve, and the effect of dust on the upper air-tract can be modified by passage and enforcement of sane laws.

We should join heartily in the propaganda for medical and popular education and form a society of human animal welfare that will take precedence over that organized for the dog and the automobile. When the science of prevention fully arrives, every human machine will be examined semiannually and a careful record kept in card index form about every organ in the body including the nose, throat and ear.

The greatest sign of the times that operates for the prevention of disease is the gradual elimination of medical sects and the elevating of medical educational standards. The osteopathic, botano-eclectic or homeopathic otolaryngologist has been relegated to otolaryngologic Pompeii and is now metamorphosed into a broad, liberal-minded nose, throat and ear surgeon who can think as a pathologist, internist or therapeutist as the occasion requires.

It is a well-known fact that abuses to the metabolic functions, though expressed in the apparatus under our special observation, will affect others through the medium of the connecting branches of the sympathetic system. The neuroses, psychoses and other disturbances of the ductless glands and vasomotor system may be prevented only by the proper hereditary development of a stable vasomotor system with stable ductless glands. Proper environment, education, control of the nervous system and good immunity must be added factors.

The practical application of the laws of prevention concern us in a small measure at present as compared with the otolaryngologist of future decades. As infection is the all-important etiologic factor of acute and chronic pathologic change in the structures under consideration, the prevention of disease becomes a problem of great individual scientific interest in quarantine, sanitation, hygiene, immunity, heredity and sociology.

Can we prevent deafness, hypertrophic rhinitis, pathologic tonsils, adenoids or accessory sinus disease? How much are we interested in the study of insect carriers? Do we realize that the house-fly can carry active tuberculosis germs from the sputum and deposit active tuberculosis germs on our food?

---

* Chairman's address, read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, June, 1914.

we keenly alert to the possible dangers to our community of the suppurating ear of the ex-scarlet fever patient, or from the throat or ear of the diphtheria carrier? Do we take cultures from acute infections?

The prevention of disease of the accessory sinuses has become more difficult by the laws of evolution that made the postural change in man from a quadruped to a biped. Many unchangeable, etiologic factors of prenatal or postnatal structural origin make prevention difficult. Anthropology tells us that the modern Caucasian bears many marks of asymmetry or abnormal development that attend our higher civilization and departures from aboriginal conditions.

The medical inspection of schoolchildren has given the otolaryngologist a splendid field of statistical study and observation along the lines of prophylaxis. It would seem that the scientific fruit of this labor should be forthcoming in some future program.

What methods or theories have we evolved that will lessen the enormous number of pathologic tonsils and adenoids? We know that the nasopharynx and nasal passages, in infancy and childhood particularly, are the seat of constant histologic change. Under degenerative laws of disuse such as the olfactory sense, atypical structural integrity and lowered heredity and physical and moral standards, a direct tendency to pathologic change is encouraged. It is asserted by radicals, therefore, that as the adenoid is a menace and the gateway of infection, preventive measures demand in every case a thorough prophylactic operation in infancy. This ultraradicalism may be progressive and justifiable in the future, but watchful waiting in the absence of symptoms seems a more reasonable policy in the light of our present knowledge.

The faucial tonsil as an embryologic remnant deserves further research. Its function remains in the realm of speculation and theory and the immediate and remote effects of its infection are thoroughly and generally realized, yet the wanton destruction of any structure will bring a reaction. We must, therefore, temper our procedure with judgment and skill, and operate under the rules that we would apply to our own flesh and blood.

When devotion to medical research and education in our particular realm shall unravel the mysteries of infection and the artificial and biochemical production of immunity, when the internal secretions may be regulated at the will of the therapeutist, the otolaryngologist will assume his greater rôle in the broad field of endeavor of preventive medicine and therapeutics. Major nose, throat and ear surgery will remain exclusively for the man of surgical mind, training and ability.

As the millenium has not arrived we must work on in our field of special choice under the optimistic banner, "We will do the best we can."

32 Adams Avenue.

The Creative Mind.—It is in the putting forth of the hypothesis that the true man of science shows the creative power which makes him and the poets brothers. His must be a sensitive soul, ready to vibrate to Nature's touches. Before the dull eye of the ordinary mind facts pass one after the other in long procession, but pass without effect, awakening nothing. In the eye of the man of genius, be he poet or man of science, the same facts light up an illumination, in the one of beauty, in the other of truth; each possesses a responsive imagination. Such had Bernard, and the responses which in his youth found expression in verses, in his maturer and trained mind took the form of scientific hypothesis.—Foster.

ACUTE INSULAR SCLEROSIS AND ITS CONCOMITANT VISUAL DISTURBANCES *

FOSTER KENNEDY, M.D., F.R.S. (EDIN.)
NEW YORK

Man does not live by bread alone, but also by catchwords: and, too often, faulty diagnoses come through the attempt to apply to many types of the same disease a hide-bound ritual, a uniform formulary, a triad or pentad of mechanical tests laid down in text-book after text-book as "classical" and thereby conclusive. Of no abnormal state can these strictures be more properly made than of the familiar and obscure entity introduced to the world by Charcot as *sclérose en plaque*.

The clinical picture of this condition with which the printed word has made us familiar is that of a chronic disease characterized by a spastic paraplegia, nystagmus, so-called scanning speech and intention tremor—which latter, by the way, is no tremor in any sense of the word but is rather a true motor ataxia of purely cerebellar origin. Such are the requirements demanded of the disease by undergraduates and the majority of practitioners; the dogmatic authorities often fail to point out the essential fact that these symptoms are in no way necessary for diagnosis, that they occur only in a certain number of cases and, usually, in these at but a very advanced stage, and that they are mainly dependent for their production on a disturbance of the ponto-cerebellar fibers—a more or less casual occurrence.

The diagnosis should depend on a consideration of the age of the patient, on the history of the disease, and on the grouping of the symptoms rather than on the presence or absence of individual abnormalities of function. These are probably the result of transient edematous phenomena occurring irregularly throughout the central nervous system.

The vagueness of many pathologic terms is studied and is necessitated by our ignorance of the precise processes on which depend the early symptomatology of this disease.

The sclerosed tissue is invariably in the immediate neighborhood of blood-vessels, and the first step in the morbid process is apparently a flooding of the nerve-cells and fibers with fluid exudate, the vessel wall having been weakened and rendered permeable by the agency of a toxin or virus as yet unknown. Only by the hypothesis that such an edema exists can we explain the rushing onset and the rapid remissions and recoveries of some of these cases. The occurrence of such processes can only be assumed, in that post-mortem examinations are possible in the majority of instances only after the disease has long become chronic.

The scattered islets of hypertrophic glia are of doubtful causation; and no exact proof is forthcoming as to whether they are the expression of a primarily parenchymatous disease or of an inflammatory process affecting in the main the interstitial tissue. The clinical course of the disease as exhibited by its remissions and intermissions, its transient amblyopias, transient paralyses and transient attacks of subjective sensory manifestations occurring in its incipiency,

* Read before the Section on Nervous and Mental Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

Dr. Robert Bell Library
E. M. E. Medical College 29502

movement of the eyeballs has reappeared and is rapidly improving in all directions. It is accompanied by gross nystagmoid jerking. All movements are present in both the upper and lower limbs; those on the left side are stronger than those on the right. Gross loss of sense of position in all four limbs. No other sensory change.

June 11: Rapidly improving.

July 3: Pupils normal. Conjugate movement of eyeballs almost complete. Convergence impossible. Palatal reflex normal. Markedly emotional. All movements are present in all four limbs which are, however, both spastic and ataxic. Sense of position absent in upper, and impaired in lower extremities. Reflexes as before.

August 25: Improving daily. Diplopia is now present in distant vision, consequent on marked return of visual acuity. Speech scanning, syllabic, and explosive. Emotional. Ataxia in all four limbs but more marked on the left than on the right side. To-day attempted to stand. Astereognosis in both hands. Sense of position absent in the right wrist and fingers; also in fingers of the left hand. Reflexes as before. No rectal incontinence now. Is incontinent of urine about once a week.

September 28: Improving daily. Walks the length of the ward without help. Very slightly ataxic. Sphincters normal. Beyond changes in the optic disk there is now no trace of any previous involvement of the cranial nerves.

I have purposely omitted detailed mention of the behavior of the optic nerves and the consequent fluctuations in visual acuity. In such a cloud of symptoms as was shown by this patient it would be difficult closely to follow the various changes found in the optic disks; for this reason they will now be described separately.

On admission, as has been said before, patient was unable with the right eye to see a moving light. With the left eye the candle could be seen in the periphery of the field. Optic disks: Right: doubtful blurring of the inner edge. Vessels normal. Left: a rather dead-looking pallor in the outer temporal quadrants.

May 3: Right: veins considerably distended. All edges are blurred with the exception of that on the outer side. Color normal. The pit is naturally somewhat small—there is some whitish tissue in it which is possibly developmental. Hypermetropia plus 2 D. Disk seen with plus 3 D. Left optic disk as before.

It is to be remembered here that five weeks previous to this examination there was almost complete loss of vision in the left eye, a condition now rapidly developing in the right eye as well.

It is to be presumed that an ophthalmoscopic examination of the left disk carried out at the end of February would have revealed a venous distention and a blurring of the disk edges similar to the phenomena seen in the right eye in May. The condition seen in the left disk was a result of a previous inflammatory state which later occurred in the right optic nerve as well. Two types of congestive phenomena may occur in the optic nerve—the papilloedema consequent on increased intracranial pressure, and that known as retrobulbar neuritis.

The first is a purely mechanical condition, in which cerebrospinal fluid is forced from the main reservoir of the ventricles and the intradural space down the vaginal sheaths to appear at the point of lowest resistance — the nerve-head, whence it is drained into the sclera at a rate which varies with the type of formation of the eyeball—more rapidly and more effectively in myopic than in hypermetropic eyes. The second condition, however, has to do, not with the water-jacket of the optic nerve, but with the fibers themselves. As indicated by its name, the morbid process takes place posterior to the globe, is a true inflammation, and its occurrence is accompanied from the beginning by rapid loss of function in the affected fibers which lie in the bony walls of the optic canal. This loss in visual acuity is produced at first by the deterioration in the macular bundle which has as its consequence a central scotoma. Owing to the rigidity of the environment of the nerves, a degree of pressure will be produced which will quickly interfere with function; and, for the same reason, the degree of fluid transudation in the nerve-head will be less than is found in the mechanical abnormality first mentioned. In the latter, loss of visual function occurs but late in the disease and takes the form of a gradually increasing concentric contraction in the fields due to an organization of the edema into connective tissue. It follows, therefore, that as, in the case of retrobulbar neuritis, fiber constriction is produced by fluid exudate, and, in pressure papillo-edema, by solid connective tissue, the chances of recovery from blindness due to the former are much superior to those from blindness due to the latter.

This power of recovery, after the total destruction of vision, was admirably shown in the case under consideration, and it may here be said that permanent loss of sight practically never occurs as a result of insular sclerosis, however acute may be the initial seizure.

May 7: All the edges of the right disk were blurred except a small portion at the outer margin equal to a fifth of the total circumference of the disk. The veins and arteries showed little change in caliber. Swelling has increased by plus 2 D. An edematous appearance is seen spreading to the retina from the disk at the upper, inner, and especially the lower margins. Inner vessels slightly buried. Left optic disk: pale and unswollen.

Three days later: Right: whiter in temporal quadrants, outer edge fairly clear, vessels very small. Left disk as before.

May 17: Right: Swelling reduced by 2 diopters. Color pale. Left as before. Patient can count fingers at a distance of 3 feet with the left eye, but with the right can only distinguish an electric lamp if it be held in the periphery of the field.

May 28: Right: edges visible, blurring only in the upper and inner margins. Swelling almost gone. Color pale. Arteries very small.

June 7: Right: disk clear-cut with the exception of a woolly patch on the inferior temporal edge.

July 23: Both disks pale. Can count fingers on both sides.

August 25: Visual acuity: Right 6/30, left 6/20.

September 28: Right 6/12, left 6/12.

Case 2.—My second case is that of a Russian Jewess, aged 26, whom I saw in consultation with Dr. Frederick Peterson and Dr. Held, in the latter part of February, 1912. She had been married five years and had two healthy children. No history of lues. The Wassermann test in the blood-serum was twice found to be negative.

Present Illness.—Previous to May, 1911, her health had always been perfect. In that month, after a steam bath, she noticed that her legs were weak; they both felt numb. These symptoms appeared rapidly—within half an hour they assumed definiteness—and progressed in severity for two days, during which time she was also dizzy and complained of much blurring of vision in both eyes, with occasional diplopia. This entire attack lasted two weeks, by the end of which all trace of ailment had quite disappeared, so that she was thought by many to have gone through a hysterical seizure. Her recovery was such as to allow her to take up with much vigor the management of her shop, on which for four months she expended much physical and mental work. Again she had a sudden attack of blurred vision, which ended in complete loss of sight for two or three days' time. No sooner had partial vision been restored than she noticed in the glass one morning that the right side of her face was flattened and immobile and that she could no longer wink with the right eye. In other words, she had developed a complete right facial palsy of peripheral type. On the day of this observation she again had diplopia, the cause for which was seen on the same evening in a marked weakness of her right external rectus muscle. This situation was not maintained for long; her diplopia was replaced by another fleeting attack of blindness, during which she began to complain of numbness in the fingers of the left hand, which was in turn quickly followed by weakness and unsteadiness in both the extremities of the left side. This left-sided hemiplegia did not improve; it became more severe. Much diplopia and vertigo and frequent paresthesias in the fingers and toes of both sides were present, choking attacks made their appearance in January, 1912; in these respiration became slow and sighing, and the pulse dropped to between 45 and 50 a minute.

Examination.—The ocular fundi showed well-marked pallor in the temporal quadrants of both papillae—clear proof of the retrobulbar origin of the attacks of blindness. The physiologic pits were not filled in, nor was there any evidence of disturbance of retinal pigment. The pupils reacted briskly to light and on convergence but had poor muscular tonus. The right external rectus and the right side of the face were almost completely paralyzed. The left fifth nerve was affected, as shown by a deviation of the lower jaw to the left side on opening the mouth, and by a poor contraction of the left masseter as compared with its fellow on the right side. The soft palate was immobile; its reflex was absent but its sensitiveness was retained. The voice was very weak and was nasal in quality. There were regurgitations of fluid through the nose. Almost complete spastic paralysis of the left arm and leg. The right foot was dropped, owing to a flaccid palsy of the anterior tibial muscles. Patient was completely incontinent of both urine and feces. No sensory change could be made out, but this was perhaps owing to the impossibility of obtaining the patient's cooperation.

Course.—She succumbed to respiratory failure—a typical medullary death. Permission for necropsy was not obtained.

In this case the early symptoms pointed unmistakably to the pons as the main seat of the trouble; the possibility was considered of its nature being neoplastic rather than edematous and sclerotic, but that alternative was negatived by the ocular symptoms and especially by the ophthalmoscopic findings. The symptomatology was parallel with that in the first case and the issue would most probably have been similar had not the acuteness of the condition discounted the woman's resistance. To these two cases may be added a short account of a case that I saw in the service of Sir William Gowers.

Case 3.—A man, aged 22, Aug. 16, 1909, had diplopia, vertigo and dimness of vision in both eyes, which was progressive, so that on August 24 he could distinguish form only in the periphery of both visual fields. The pupils had marked retrobulbar reactions. Optic disks showed a low-grade swelling on both sides.

August 27: Pupillary reactions poorer and some limitation of conjugate ocular movement upward.

September 1: The light reflex, from being almost imperceptible, is now fair. Ocular movements almost normal again. Vision worse; patient now only able to perceive peripherally placed lights.

September 9: Patient can again recognize physician's hand.

September 24: Patient is able to count fingers at 3 feet distance with each eye; central scotomas maintained.

October 4: Numbness in the left leg; left-sided ankle-clonus and left extensor plantar response. Optic disks; pale in outer quadrants. No swelling.

October 6: Retention of urine. Numbness in right hand.

October 11: Rapid onset of spasticity in both lower extremities.

October 13: Complete bladder and rectal incontinence. Vision: Right, 1/36; left, 1/60.

October 14: Numbness in both hands.

November: Weakness in right arm. Central scotoma in each eye. Complete paraplegia with sphincter palsy.

Repeated examinations of the cerebrospinal fluid failed to show any abnormality. This with a negative history served to exclude cerebrospinal lues.

In all these cases there were marked fluctuations in the severity of the symptoms; in none could the clinical picture be said to correspond with the textbook descriptions of the disease; but the symptom grouping and the variability of progress in each case left no room for doubt as to the correctness of the diagnoses.

20 West Fiftieth Street.

ABSTRACT OF DISCUSSION

Dr. George A. Moleen, Denver: It is to be noted that the cases reported by Dr. Kennedy were drawn from the country in which multiple sclerosis is most frequent. Our German friends would have us believe that many of these cases are really cases of syringomyelia and are not seen in this country so frequently. We generally hold that with such degenerative processes as multiple sclerosis characterizes we find retrobulbar atrophy more frequently. I am glad to hear suggested an explanation of the papilledema, even a primary hyperemia or a primary sero-edema, however localized. The majority of cases of multiple sclerosis which one sees here shows limited fundus changes, and yet I do not believe that they are searched for with the care which their importance demands. I do not believe I have ever seen a case of edema in multiple sclerosis. Dr. Prentiss and I, in the National Hospital, discussed the question whether it was the rule to find edematous changes in the papilla in association with diseases of a purely degenerative character with a generally negative inclination. Dr. Kennedy's findings are interesting if based only on clinical evidence. As I understand it, there was no necropsy in these cases. It would be very interesting to know, as a departure from the idols which we hold with regard to degenerative diseases, whether or not there was, in association with those symptoms, a possible neoplasm, or at least something which we believe to be at the basis of most conditions of papilledema, that is, increase of intracranial pressure.

Dr. Peter Bassoe, Chicago: Will Dr. Kennedy state the frequency with which optic neuritis occurs in the early stages of disseminated sclerosis? I am inclined to think that there is a stage of optic neuritis in many of these cases before the familiar pallor of the disks sets in. I recall a case of a young woman with no physical signs of organic disease who suddenly became blind in one eye. There was a distinct hyperemia of the disk, but an able ophthalmologist stated that it was not necessarily beyond physiologic limits. The patient was treated for hysteric blindness and recovered her sight, but a year or so later she developed the ordinary signs of disseminated sclerosis. In another case which I examined only post mortem I found typical lesions of disseminated sclerosis including marked changes in the optic chiasm and optic nerves. There was a history that an ophthalmologist had found a choked disk at a very early stage.

Dr. William W. Graves, St. Louis: Has Dr. Kennedy in his recent study of the literature found many cases of multiple sclerosis in which the optic nerves were involved to the extent of complete atrophy?

Dr. Foster Kennedy, New York: Dr. Moleen suggests that these cases might possibly be neoplastic. This possibility, as indicated in the paper, was considered at the time. In Case 1 the patient went through a series of events which came out extraordinarily quickly, each phenomenon appearing in a way that is not usual in neoplasms. Further, his recovery from all those acute symptoms was almost complete. From being in a state practically dead, he recovered to a very considerable degree of efficiency. The fact that he lived and that his symptoms disappeared, would seem to do away with the possibility of neoplasm. The patient in Case 2 died. The only direct evidence we had that this was not neoplasm of the pons was the fact that the woman had very marked pallor in each disk; a retrobulbar condition which could not be explained by a pontine tumor. In Case 3 the man's symptoms began as a retrobulbar neuritis with scotomas, progressed to bilateral paresthesia in the hands and ended with a well-marked middorsal lesion in the spine. Dr. Bassoe asked concerning the frequency of optic neuritis in sclerosis. At some stage of the process, retrobulbar neurtis has been present in most cases to some degree; but practically every case of advanced disseminated sclerosis shows a varying degree of pallor of the disks. That can only be brought about by degeneration of the macular bundle, and that degeneration is produced by an area of edema in the course of the optic nerve. This is true optic neuritis, and while Uhtoff says that 50 per cent. of the cases of disseminated sclerosis show optic neuritis, I wonder if he does not mean that in half of the cases of disseminated sclerosis is found temporal papillary pallor. Answering Dr. Graves' question as to the production of permanent blindness in disseminated sclerosis, owing to lack of time I was silent on that question. I state in the paper, however, that the first patient's visual progress, his complete blindness and the recovery of his sight afterward to a very considerable degree, is only a quantitative variation of the progress that I am accustomed to look for in severe cases of this disease. I think one may lay it down as a fact that permanent bilateral blindness does not occur as a result of disseminated sclerosis.

DIFFERENTIAL DIAGNOSIS OF NEPHROLITHIASIS AND RENAL TUBERCULOSIS BY ROENTGENOGRAPHY*

MARTIN KROTOSZYNER, M.D.
SAN FRANCISCO

The differential diagnosis of renal tuberculosis and lithiasis is, at present, in the great majority of cases easily accomplished by the trained urologist. The positive evidence obtained from a good roentgenogram establishes at once the diagnosis of calculus, and if in a cachectic individual with suspicious lung-symptoms a protracted and distressing pyuria exists, the diagnosis of renal tuberculosis can be ventured, though tubercle bacilli may not be traceable in the bladder-urine. Thus a correct recognition of both pathologic conditions is, in many instances, feasible by the general practitioner who has taken the pains to familiarize himself with the routine technic of modern urologic diagnostic methods.

Roentgenography is at present justly recognized as the most important means of diagnosing renal calculus, and a satisfactory kidney-plate demonstrating one or more characteristic calculus shadows is now, especially since the more general use of the compression diaphragm, feasible even at the hands of the country practitioner. The risk, besides that, of overlooking or not recognizing concrement shadows can be considerably reduced by the repeated roentgenographic examination of patients with suspicious symptoms of the upper urinary tract.

It is, therefore not surprising that indications for operative procedures in alleged renal lithiasis are, in many quarters, based solely on positive plate-findings. That this must often lead to disappointment and failure is apparent from the fact that, according to a recent review on the value of roentgenography for the diagnosis of urologic lesions, from Immelmann's laboratory[1] thirty-two possibilities of erroneous plate interpretation exist, by which the roentgenographic stone diagnosis is rendered unsafe at the hands of the uncritical and inexperienced observer.

PREVIOUS LITERATURE

While thus the diagnostic importance of roentgenography seems to be over-estimated as regards nephrolithiasis, its value for the recognition of renal tuberculosis, in the absence of clinical or laboratory evidence, is not yet sufficiently appreciated. The literature contains but scant data on the Roentgen diagnosis of tuberculous kidney conditions. Casper[2] and Forsell[3] were able to recognize on the plate tuberculous parenchymatous changes (cavities); a mottled appearance of the kidney shadow is according to Hoffmann[4] and Holland,[5] characteristic of tuberculosis, and irregularities in the density and contours of the kidney shadow are considered by Cole[6] as well as by Proust and Infroid[7] as significant of inflammatory tuberculous foci. An abnormally large kidney shadow may, according to Arthur Hoffmann[8] be characteristic of tuberculosis. More important, because of definitely practical value, is the Roentgen diagnosis of calcified tuberculous foci within the renal shadow. These calcifications, the smallest of which may cast perceptible shadows on the plate, are, according to Burchard,[9] generally located in the lateral portions of the kidney and have only rarely been found in the region of the pelvis or calices. By their location on the plate as well as by their indefinite contours they can, as pointed out by the same author in his exhaustive review on this subject, readily be differentiated from calculus-shadows. Von Lichtenberg and Dietlen[10] consider pyelography of definite value in the local diagnosis of renal tuberculosis as permitting of an exact anatomic orientation on the character and extension of the destructive process of renal parenchyma. An important contribution to the Roentgen diagnosis of renal tuberculosis was lately presented by Söderlund,[11] who reports three cases with characteristic plate-findings, from which alone he was able to make a correct local diagnosis which was afterward verified at the operation.

TUBERCULOUS PUTTY-KIDNEY

A critical review of the literature concerning the plate diagnosis of renal tuberculosis forces on us the conclusion that its real and practical value lies in its differential diagnostic aspect with regard to nephrolithiasis. The importance of a correct differential diagnosis is the more obvious since, not infrequently, the other clinical methods of examination either cannot be applied or fail to yield diagnostic evidence. In these cases plate-findings may be of the utmost diagnostic importance as the only means of disclosing the seat, extension and character of the lesion. As regards the roentgenographic differentiation of tuberculous calcifications from lithiasis, the partial or total so-called putty-kidney (*Kittniere* of the Germans) presents such definite and characteristic plate-features, that on its basis alone a correct diagnosis may be feasible. Through the kindness of Dr. H. M. Sherman of San Francisco, to whom I herewith wish to express my thanks, I am able to present a beautiful roentgenographic specimen of a total putty-kidney, which is the more instructive from a differential-diagnostic standpoint, since it combines the classical features of roentgenographic tuberculosis and lithiasis (Fig. 1).

The illustration represents the roentgenogram of the right kidney and ureter of a man of 38, who in 1907 came under Dr. Sherman's observation at St. Luke's Hospital, San Francisco, with a history of pyuria and frequent and painful micturition of twenty years' duration. A roentgenogram of the right kidney region demonstrated a huge shadow of unusually intense density and of the size and shape of an enlarged kidney shadow, and a less dense well-defined characteristic calculus shadow impacted in the ureter about 4 cm. below the upper shadow. The right kidney and upper part of the ureter was removed. The wound healed properly and the patient's symptoms gradually abated so that at his discharge from the hospital four months later, he was passing urine but seven or eight times in twenty-four hours. The removed kidney showed marked caseation. The ureteral calculus was 2 cm. long.

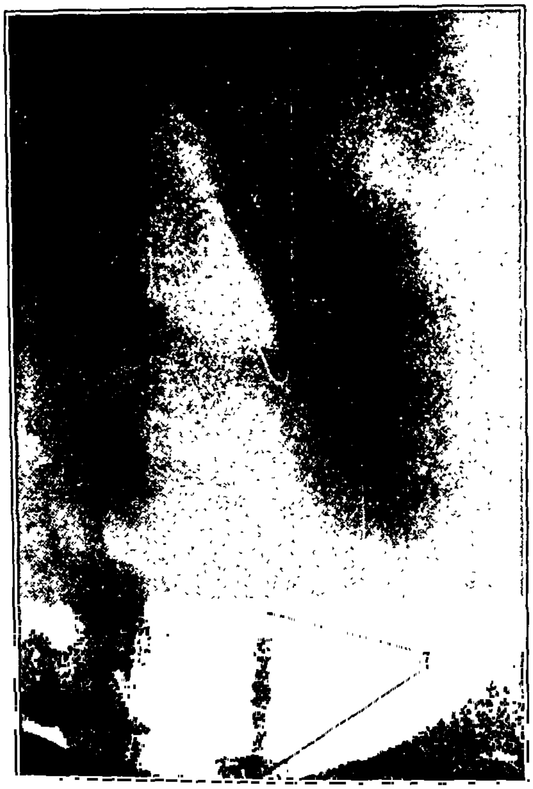

Fig. 1.—Tuberculous putty-kidney. Calculus in ureter at *A*.

I can find the record of only a few similar observations in the literature. The first case of a roentgenographically recognized partial putty-kidney was reported by Forsell and Josefsson[12] in 1908. Two years later Hürter[13] published the first plate of a total putty-kidney, in which the diagnosis of marked tuberculous calcifications of the right kidney and ureter was afterward verified at the post-mortem examination, when the parenchyma of the right kidney was found to be replaced by large cavities filled with cheesy material. Quite recently two cases of total putty-kidney in which the operative indications were based solely on roentgenographic findings afterward proved to be correct at the operation, were reported by Söderlund.[11]

The plate represented by Figure 1 permits of a correct diagnosis through the marked difference in density between the two shadows. The lower oblong, equally dense, and well-defined shadow is, obviously, the photograph of a calculus. The upper denser and, on account of its ragged edges, somewhat irregular shadow, shows an unequal intensity of density suggestive of being cast by disorganized and incrustated material and not by homogeneous concrement substance. The plate is, therefore, a unique specimen of total tuberculous putty-kidney, combining the skiagraphic features of tuberculosis and lithiasis and thus demonstrating, at a glance, the value of roentgenography for the differential diagnosis of both conditions.

SCATTERED CALCIFIED FOCI

While though, in this instance, the diagnosis could be fairly well read from the plate, there are cases recorded in the literature with shadows on the plate resembling concrement-shadows, the differentiation of which from tuberculosis, in the absence of other clinical and bacteriologic evidence, is either very difficult or actually impossible. Occasionally patients enter the hospital with symptoms pointing to lithiasis and demanding immediate action, where in the interpretation of shadows on the kidney-plate the possibility of an existing tuberculosis should always be borne in mind. The following observation will serve to illustrate the point:

In the earlier part of 1908 I was summoned to a man of 41, whom I found in deep uremic coma. Complete anuria; bladder empty; high temperature; rapid and compressible pulse, kidneys not palpable. No data on the previous history could be ascertained. A tentative diagnosis of calculous anuria was made which appeared to be obvious, when two concrement shadows were noticeable on the plate of the left kidney-region (Fig. 2).

The patient was rushed to the hospital where the left kidney, on exposure, was found to be considerably enlarged, containing a pus-cavity at its upper pole, while in the center of the organ two small cavities filled with cheesy material were found. The kidney was, therefore, removed. The patient died the next day without voiding urine or regaining consciousness. The right kidney was found, at the post-mortem examination, to be small, presenting the typical picture of tuberculous atrophy. Renal function, in all probability, had been maintained by the left kidney, the enlargement of which was, obviously, due to compensation.

While the diagnostic error in this case was excusable, on account of the absence of other clinical evidence, a critical perusal of the plate-findings, done with the caution, at present considered indispensable in the interpretation of concrement shadows, might have aroused doubts in the diagnosis. The striking difference in the density, the demarcation and shape of both shadows points to the existence of different shadow-casting substances, which is not characteristic of lithiasis. Particularly the dimness and spotted appearance of the lower shadow with its indefinite edges would to-day, in the hands of the experienced observer, lead to the rejection of the stone diagnosis.

It is very doubtful, however, whether the positive diagnosis of tuberculosis could be made on the basis of these plate findings. The correct interpretation of suggestive concrement shadows is very difficult even in the presence of more or less characteristic features pointing to tuberculosis. When these are absent, though, the resemblance of tuberculous foci to calculi shadows is so striking that a correct plate diagnosis is well-nigh impossible, as in the following observation:

---

[12] Forsell and Josefsson: Hygiea, 1912.
[13] Hürter: Ztschr. f. Roentgenkunde, 1910, No. 11.

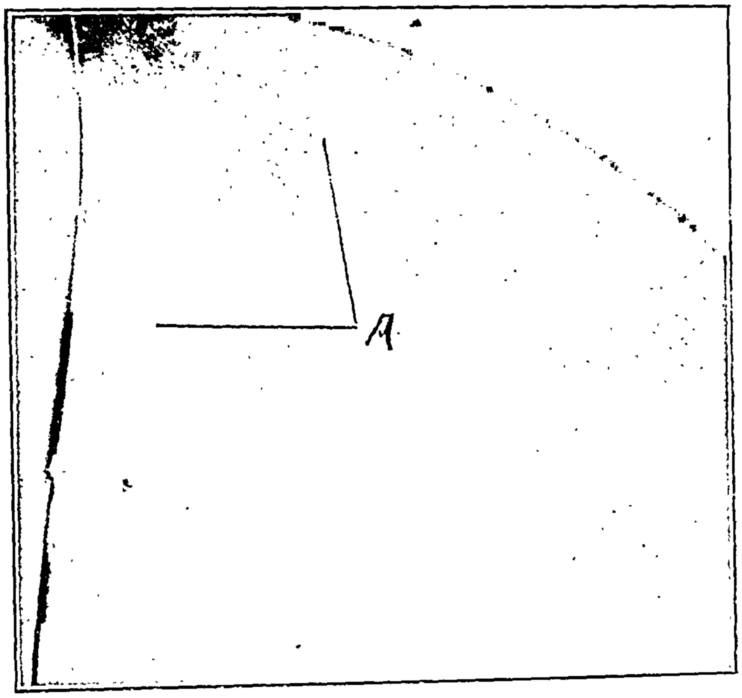

Fig. 2.—Calcified tuberculous foci at *A*.

A stout woman of 44, of excellent physique, had suffered for the last eighteen months from attacks of typical right-sided kidney colic and frequent and painful micturition. Repeated urinalyses demonstrated a moderate amount of pus and blood and no tubercle bacilli. At the hospital the physical examination, including kidney palpation, proved negative. Cystoscopy showed a perfectly normal bladder, except for a moderate cystitis coli, and no abnormality in appearance and spurt of either ureter. The urine of the right side was slightly cloudy and contained, microscopically, pus and blood in moderate amounts, while the secretion of the left kidney was normal in appearance and microscopically. The various functional tests showed good values on both sides, in fact a slight but uniform superiority of function of the suspected right kidney (sugar after phloridzin 1.2 on the right against 1.0 on the left side, etc.). No tubercle bacilli in right renal secretion. Repeated roentgenographic exposures including a pyelogram (Fig. 3) showed on the right side two small round and well-defined shadows, which were interpreted as calculus shadows.

The exposed right kidney presented, near its lower pole, two small cavities filled with a gritty, caseous material. The removed kidney showed, in the region of its pelvis, granulation and cicatricial tissue in which tubercle bacilli with giant-cells were present (chronic tuberculosis).

The diagnostic difficulties encountered in this case were unusual. Strong arguments against tuberculosis were the negative cystoscopic findings and, particularly, the functional integrity of the suspected kidney. According to Wildholz,[14] probably the best authority on tuberculosis of the genito-urinary tract to-day, the most unimpeachable evidence of the existence of renal tuberculosis is presented by a perceptible deterioration of function of the suspected organ. Thus. in the absence of reliable clinical evidence, the plate-findings, pointing to lithiasis, became of decisive diagnostic importance. The only clue to the diagnostic problem lay in the correct interpretation of the pyelographic plate (Fig. 3), disclosing hazy and irregular contours of all calices, which findings in the experience of von Lichtenberg and Dietlen[10] are characteristic of renal tuberculosis.

COMMENT ON DIFFERENTIAL DIAGNOSIS

From our present meager knowledge of the differential diagnostic aspect of plate shadows it appears that, in a great many instances, a correct roentgenographic differentiation between renal tuberculosis and lithiasis is not feasible. This is particularly true of one or more small and circumscribed shadows cast by scattered foci of tuberculous caseation. Such shadows look so much like stone-shadows, as for instance, in the case reported by Menhauser from Israel's clinic,[15] that a correct local diagnosis, on the sole basis of plate-findings, is utterly impossible. Only the tuberculous putty-kidney presents sufficiently characteristic roentgenographic features as to permit of a correct local diagnosis.

I am convinced from my own observation that pyelography may occasionally be of definite differential diagnostic value. This method, though, is too risky a procedure in renal tuberculosis to become a routine measure in doubtful cases.

Another source of error may arise from the possibility that a shadow seen on the renal plate is cast by an object outside the kidney. The shadow on the plate presented in Figure 4 is cast by a tuberculous lymph-gland removed from a patient who had suffered from typical attacks of left-sided stone-colic.

While, thus, the differential diagnosis of nephrolithiasis and renal tuberculosis by roentgenography alone is in most instances difficult and often impossible, it is, nevertheless, capable of yielding better results with growing experience in the interpretation of suspicious shadows. It is obviously true that in order to diagnose a certain lesion one has to consider the probability of its existence. If, therefore, in the presence of one or more alleged concrement shadows on the plate, the probability of tuberculosis will always

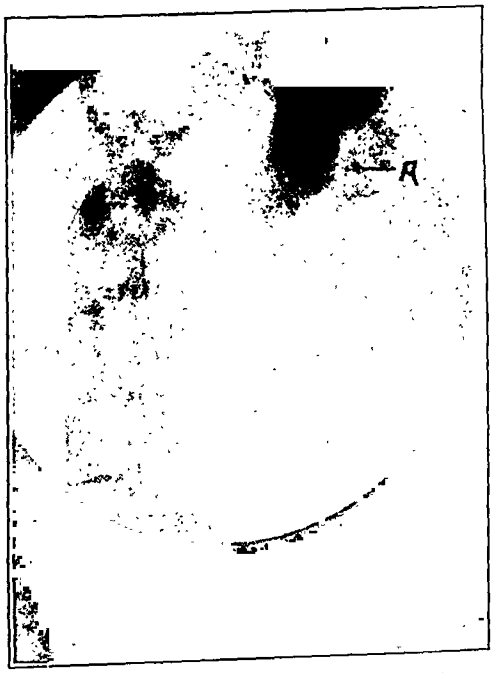

Fig. 3.—Pyelogram of tuberculous kidney. Note irregular contour of calices. Shadow of tuberculous caseation at *A*.

be borne in mind, the occurrence of diagnostic errors will in time be materially reduced.

CONCLUSIONS

1. Roentgenography may be of definite value in the local diagnosis of renal tuberculosis when other clinical methods fail.

2. The differential diagnosis of nephrolithiasis and nephrophthisis, by roentgenography alone is feasible in the presence of marked tuberculous renal caseation (tuberculous putty-kidney).

3. It is difficult or perhaps impossible in the presence of one or more concrement shadows cast by calcified tuberculous foci within the renal parenchyma.

4. A careful and judicious interpretation of concrement shadows is imperative in order to avoid diagnostic errors of serious consequence.

999 Sutter Street.

ABSTRACT OF DISCUSSION

Dr. W. M. Spitzer, Denver: None of us relies implicitly on the roentgenograms, but the more we can develop our technic and the more we can rely on the roentgenograms, the more keen our diagnosis will be. This, of course, is an argument for pyelography. We will eventually, I am sure, when sufficient work has been done, be able to diagnose from the shape of the calices and the kidney pelvis, as well as from the size of the kidney pelvis, various lesions. As to the differential diagnosis between a stone and a caseous mass in the kidney, I do not know that that can always be made. I do not think that the density counts very much. There are dense stones that do not show at all on the roentgenogram, whereas, on the other hand, there are masses of caseous material which show quite distinctly. Still, the closer attention we pay to the study of our roentgenograms, the greater aid we are going to have in making our diagnoses.

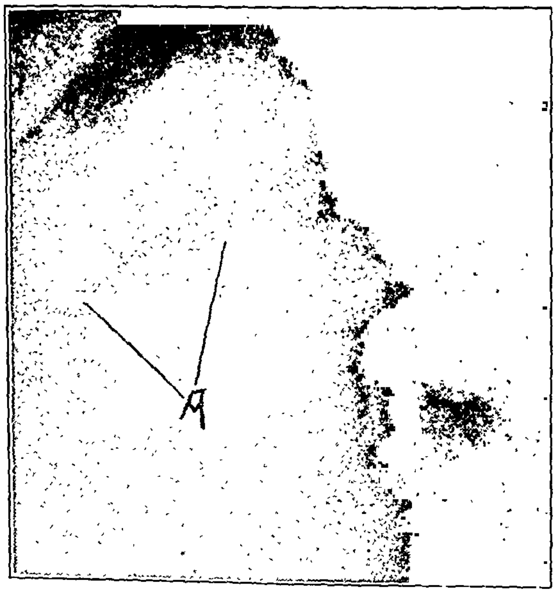

Fig. 4.—Tuberculous lymph-glands at *A*.

Dr. Martin Krotoszyner, San Francisco: Though the differential diagnosis in this instance was materially aided by pyelography, this method should, if possible, not be applied in suspected renal tuberculosis, where it is considered by good authority to be particularly dangerous.

Destruction of Mosquito Larvae by Fish.—In the Gambia the destruction of mosquito larvae by fish is systematically carried out. A constant reserve of fish is maintained at the sea end of one of the drains even in dry season, and as occasion demands some are transferred to other drains, private wells, etc. More and more private individuals are having their wells stocked with fish. This it proves a more efficient prophylaxis than well-covers, which, however thorough in themselves, must of necessity be frequently removed. Fish from the sea introduced into comparatively fresh water are some time in adapting themselves to it, but after a day or two become brisk again and destroy larvae with avidity. Whether it is this change that temporarily upsets them, or the pangs of hunger eventually asserting themselves, though some fish would not touch larvae on their first day in captivity, all fish eat them greedily from the second day onward.

THE OPERATIVE TREATMENT OF TUMORS OF THE TESTICLE

WITH THE REPORT OF THIRTY CASES TREATED BY ORCHIDECTOMY*

FRANK HINMAN, M.D.
Assistant Resident Surgeon, Johns Hopkins Hospital
BALTIMORE

A well-recognized principle in the surgical treatment of malignancy is to excise widely the local growth, to make a clean dissection of all the lymphatics which drain the area and to remove the primary chain of glands into which these lymphatic vessels empty. The mortality-rate from cancer has progressively decreased with the adoption of these more and more radical methods of attack. Simple castration has been long and almost universally the treatment for malignant disease of the testes, and the majority of these patients have been seen to die of metastases which primarily involve the preaortic lymph-nodes into which the lymph-channels of the testicle drain. The radical principle which is theoretically so rational has not been generally applied to the surgery of the testicle for obvious anatomic and other reasons. Surgeons have been restrained both by the great operative difficulties and by a general belief in the futility of such an extensive procedure.

The purpose of this study is to determine from a review of the literature and an analysis of the cases of the Johns Hopkins Hospital the true value of castration and to compare this with the results that have followed the use of the radical operation in the forty-odd cases reported in the literature. Such an analysis has never been made and should give an excellent opportunity of determining the significance of preoperative duration and rapidity of growth of the tumor to the onset of glandular metastases and the significance of such metastases with respect to a choice between the two methods of operative treatment. The particular object is to find out if the radical operation is ever justified, and if so, under what conditions.

HISTORICAL

The study of testicular tumors has been chiefly confined in the past to pathologic considerations. From this point of view these tumors are of unusual interest as they show cells and tissues of almost every conceivable variety. The subject was in hopeless riot until the appearance in 1906 of the masterly pathologic and clinical study of 100 cases by Chevassu[1] which simplified the classification to practically only two types of tumor of almost equal frequency, namely, the round-cell carcinomas and nine are teratomas. Of the former group two patients are alive, twelve and thirteen years, and none of the seven patients that are dead lived over two years. Of the latter group all are dead except one patient, who is now alive for only sixteen months. One patient lived for three years, another for nine years and seven months. This case is most unusual with a history of injury forty years before the onset of tumor which preceded orchidectomy by three years. A letter from the patient six years later (1906) stated that he was well, and a letter from his wife this summer states that he died of "abdominal cancer," March 3, 1910, nine years and seven months after castration. These facts indicate that the mixed type of tumors are more malignant, though possibly of a slower form of growth, than the pure-cell carcinomas, although, since all tumors are teratomatous in origin, such a differentiation is more or less arbitrary.

---

[1] Chevassu, Maurice: Tumeurs du testicule, thesis, Paris, 1906.

The result in the four cases in which the material was not available for study but in which a previous diagnosis of sarcoma had been made gives one living now almost twelve years, and three deaths, one, two and eight years, respectively, after castration. The latter case is another remarkable instance of the long duration of life that is possible after castration for teratoma testes with ultimate death from cancer metastases. It is that of a cryptorchid who three years following double castration, at which time both testicles were found to be the seat of "sarcoma," began to have abdominal symptoms, but lumbar glands were not palpable until after six years, and death did not occur until eight years after the operation. Bloodgood places the time limit for cure in cancer of the breast at eight years, and it would seem that the limit of four years as placed by Chevassu, while only exceptionally exceeded, is not an absolutely safe period in cancer of the testes. One of Chevassu's own patients died a full four years after operation; but, as Andrews formulates it:

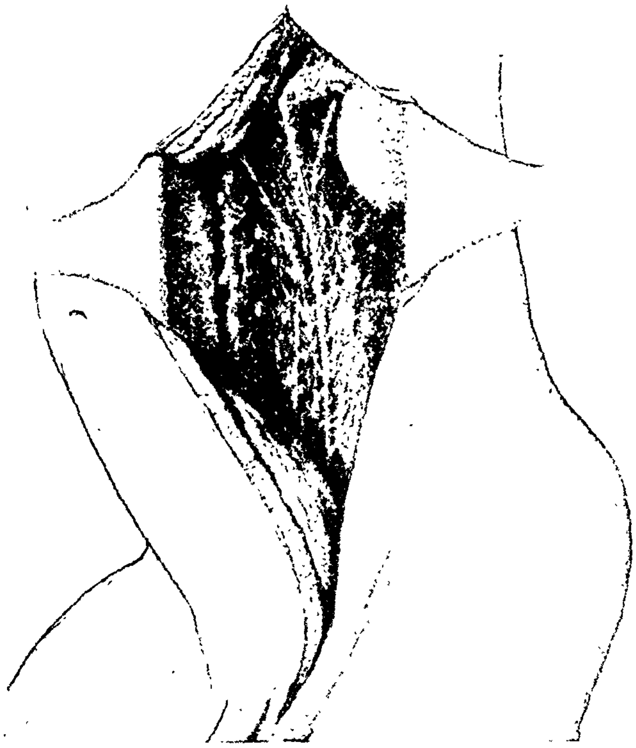

Fig. 3.—Peritoneum stripped back showing lymph area to be removed.

> The risk of recurrence in malignant growths increases as the square of the time of growth; or, conversely, the risk of recurrence diminishes in the ratio of the square root of the time after incidence.

With one exception in which death resulted a few days after operation from pulmonary embolus, all of the patients, so far as can be determined, died of cancer. Excluding this one case of embolus and the four cases in which metastases were already present at the time of operation, the series shows a cure from castration in only 15 per cent. of the cases, a high mortality-rate of 85 per cent.

ANALYSIS OF CASES TREATED BY RADICAL OPERATION

The records of forty-four attempts radically to remove the primary preaortic lymph area in treating testicular tumors have been collected from the literature. Gregoire furnishes information regarding two additional and unpublished cases. This material offers an excellent opportunity because of the exposure at operation to determine the relation of the duration, size, rapidity of growth and the character of the tumor to the onset of the glandular metastases and their early location. Inasmuch as thirty-two of the operations were performed before 1911, there has been sufficient time to allow of a comparison of the results with those following castration. Several French theses have been written on the subject (Calin,[12] Beckerich,[13] Moscarenhas[14]), but in none of these are the cases analyzed to show the operative or ultimate mortality, the relative number of cases which had at the time of the operation early metastases and the proportion of these in which these metastases, although not possible of recognition clinically, were so extensive as to be inoperable.

The technic of the operation from a study of the descriptions of the various operators and from personal dissections from which the accompanying drawings have been made is briefly as follows: The operation is usually performed in two stages, inguinal and abdominal. The first stage is that of ordinary castration and it is extremely important that the testicle be carefully examined at this time and the diagnosis definitely confirmed before proceeding to the extensive abdominal part of the operation. The fact that over 7 per cent. of the few cases so far subjected to the radical method of treatment were found on subsequent examination of the specimens to have had a syphilitic orchitis shows the importance of this preliminary study.

For the second stage of the operation the position of the patient is of considerable importance. It should be a bent dorsolateral one with the patient turned partly on his back and resting on a pad under the costal margin with shoulder and hip on the table. This raises the spine to conform to the line of the incision and allows a good exposure of the deep abdominal vessels (Fig. 2). The skin incision is extended from the upper end of the inguinal cut parallel to Poupart's ligament, curving upward in the axillary line at about 4 cm. below the anterior superior spine of the ilium to end at the costal margin. In fat, thick-bellied men, the upper end of the incision may be extended along the rib margin either anteriorly (Gregoire, Fredet[15]) or posteriorly (Cuneo). The muscle-fibers and fascia are divided in a line with the skin incision down to the peritoneum, which is gently stripped back so as to expose the lower pole of the kidney and the psoas muscle. A choice is given the operator between starting above at the renal pedicle and working down or beginning below in the inguinal ring and stripping the cord and vessels up toward the lumbar region. The former method of attack appears more rational, and in the dissections by traction on the spermatic vessels at the external ring was easily accomplished. Figure 3 indicates the exposure of the lumbar field and Figure 4 the appearance after the lumbar and iliac fossae have been stripped. In cleaning the anterior surface of the aorta the inferior mesenteric artery must be protected. The spermatic vessels and the ureter usually remain attached to the peritoneum when it is stripped up in the iliac fossa, and this region should be carefully cleaned as metastases often occur where the ureter crosses the iliac vessels. The dissection should also be carried up so as to include the region about the bifurcation of the aorta. The vas deferens is readily located and divided as it leaves the internal ring. The clean removal of the vascular and lymphatic layer as outlined is far superior to the palpation and individual removal of single glands, as is sometimes described. The operation for right-sided involvement offers greater difficulties in that the area to be cleaned covers the vena cava. Good and sufficient drainage should be established owing to the large lymph area removed.

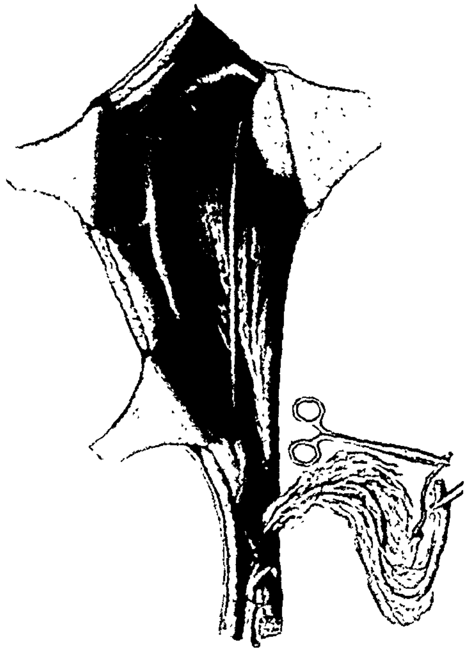

Fig. 4.—Lumbar and iliac fossae stripped clean of glands and fascia with the spermatic vessels down to inguinal ring. Vas deferens entering pelvis at point where it is divided.

From the accounts of those who have performed the operation it presents neither the difficulties nor gravity that would be expected. The patients apparently stand the operation well and show no evidence of shock, and the convalescence is relatively short. The long incision is objectionable because of the danger of hernia and of the division of numerous nerves. The tenth, eleventh and twelfth dorsal nerves are always cut, and usually the lower branch of the genitocrural. Partial paralysis of the abdominal muscles results and difficulty with the bowels is encountered during convalescence. Chevassu has shown by faradic and galvanic tests that this paralysis is only temporary. There have been no fatalities from postoperative hemorrhage or other complication as a result of injury to the large abdominal vessels. Five of the patients died of postoperative complications, three of pneumonia and two of peritonitis, an operative mortality of 11 per cent., which, considering the newness and nature of the operation, is surprisingly low.

With the exception of two cases (André,[16] Georgesco and Savesco,[17] Case 2) there was no clinical evidence of lumbar metastases before operation. Three of the cases (Cuneo, Case 2, Marion, Mercadé) were mistakes in diagnosis, the testicles in each being found on subsequent examination to be the seat of a syphilitic orchitis. Of the forty-two remaining patients, twenty are living, nine for over two years; four for over four years, the longest for four years and ten months, the shortest for one month. The average time since operation on the twenty patients who are reported alive is one year and eight months. Sixteen, or 41 per cent., have died of cancer, all within one year except two, one of whom (Gregoire, Case 1) died thirty-one months and the other (Chevassu, Case 2) four years after operation.

The duration of the disease before operation varied between two months and twelve years, with an average of fourteen months. Twenty-one of the cases had a duration under one year, and twelve of these under six months. Only three cases had a duration of over three years. While lumbar glands were palpable in only two cases before operation, twenty-two, or over 50 per cent., of the cases showed cancer invasion of the lumbar nodes that were removed at operation, and in eleven of these the involvement of the gland area was so extensive as to be inoperable. In eight of the cases in which numerous lumbar glands were removed, these on subsequent microscopic examination in no case showed cancer invasion. In three cases no lumbar glands at all were found at operation. The twenty-two cases with malignant involvement of the lumbar nodes removed at operation had a preoperative duration of from two months to twelve years or, omitting the case with a duration of twelve years, which is the longest in the series and questionable, an average of fifteen months. On the other hand, the eleven cases in which no lumbar involvement was found had a preoperative duration of from three months to fifteen months, with an average of eight months. This indicates that the preoperative duration has considerable significance with respect to the onset of glandular metastases. The significance, however, cannot be definitely determined, as many cases of short duration are seen to have extensive metastases, whereas cases of an apparently long existence may have no metastases. The chances, nevertheless, of metastases not having occurred, are greatly in favor of a case with comparatively short duration. All of the eleven patients in whom the glandular involvement was so extensive as to render its complete removal impossible are dead, except two who had been observed for only one month at the last report. Of the other fourteen patients with glandular involvement but in which the gland area supposedly was completely removed at operation, seven are living, one died of pneumonia seven days after operation, and six died of cancer recurrence.

Of the eight patients with clean glandular removal but in which no involvement could be found, five are living, and three died of cancer. Two of the three patients in whom no glands at all were found are dead. Of the six cases in which no mention is made of glands, two patients are dead, one and twelve months, respectively, after operation; three are living, one, twelve and forty-eight months, respectively, and the result in one, presumably alive, is not mentioned.

---

[16] André: Cancer du testicule avec extirpation des ganglions lombo-aortique, Revue méd. de l'est., 1912, xliv, 420.

[17] Georgesco, G., and Savesco, V.: Etude anatomique et chirurgicale sur trois cas de cancer du testicule, Jour. de Chir. de Bucarest, April, 1914, iv-vi, 226.

Obviously all cures in those patients who had cancer involvement of the lumbar glands that were removed at operation will be directly due to the radical procedure, and just as obviously the radical procedure will be able to cure in only those early cases in which the invasion has not spread beyond the primary lymph zone. Simple castration will be of no benefit in either case, and will cure in only those very early cases in which the disease is confined to the testicle proper. Of the six patients living who had glandular metastases removed, one, in whom two of the glands removed at operation showed marked invasion, is now alive and well almost five years since the removal of these glands, three other patients are alive and with no evidence of recurrence for almost three years from the time malignant lumbar glands were removed, and the two other patients were alive after operation eight and one months, respectively, at the time of the last report.

SUMMARY AND CONCLUSIONS

1. Orchidectomy will cure from 15 to 20 per cent. of teratoma testes. Obviously a cure is possible only when the testicle is removed before the onset of glandular or other metastases.

2. A cure cannot be assured until nine years after operation, although the danger of recurrence after four years is very small (only three cases reported) and progressively diminishes.

3. Cancer of the testicle metastasizes in practically every case first and primarily to a limited zone of lumbar lymph-nodes which lie on the aorta for the left testicle and on the vena cava for the right, between the bifurcation of these vessels and the renal pedicle. Communication between these two groups and to deeper or more distant glands occurs only secondarily.

4. Involvement of these primary lymph-nodes may occur early or late, and the preoperative duration of the tumor in the testicle, its rapidity of growth or its size give no definite clinical indication of the onset or extent of such metastases, but the probabilities increase the longer the duration and the more rapid the growth.

5. Pathologic differentiation of tumors of the testes into embryonal carcinomas and mixed-cell types is more or less arbitrary as both are teratomatous in origin; but the former appears to be definitely less likely to metastasize, although more rapid in its growth. There are fewer cures among the cases of teratoma, although these give the longest duration before death.

6. The primary lymph-nodes are a very imperfect guard against secondary invasion, and metastases to other gland areas by way of efferent lymph-channels or by blood-vessels to thoracic or abdominal organs may occur early. Surgical treatment is of no avail after these secondary metastases have occurred. The only hope, therefore, in a radical operation is the removal of the testicle with its primary lymph area before the disease has spread beyond this zone.

7. The experience of various surgeons in a total of forty-six cases has demonstrated in suitable cases the feasibility and technical ease of the radical operation with a combined surgical mortality in all cases of only 11 per cent.

8. Radical operation should never be undertaken when lumbar metastases are recognizable clinically, and is applicable only in the fairly early cases in which the disease is apparently limited. Owing to the deep position of the glands, these cases cannot always be differentiated before operation, so that every case, in which clinically there is no invasion, is suitable for radical treatment. The operation should never be performed until after the diagnosis is confirmed.

9. Sufficient time has not elapsed and the cases are so scattered that it has not been possible to get the ultimate result in all of the patients treated radically. Forty-six per cent. are alive, one for five years; one for four years; five for almost three years; two for over two years and eleven for one year or less. There is a probable cure in at least four cases which had lumbar glands invaded with cancer at the time of the operation. Simple castration could not have benefited any of these cases, and their cure is directly attributable to the early and clean removal of the affected lymph area.

10. In conclusion, therefore, it may be stated that the early removal of the testicle with its primary lymph zone is the rational method of surgical treatment of teratoma testes, but the extensive nature of the operation and the fact that almost one-third of the cases thus treated were found to be inoperable warrants a very careful selection of suitable cases.

I wish to acknowledge thanks to Dr. W. S. Halstead for the privilege of using the material of his surgical clinic, to Dr. J. C. Bloodgood for the valuable material of the surgical pathologic laboratory, and to Drs. Gregoire, Pringle, Chevassu, Marion and others for data in regard to cases operated on, and particularly to Dr. Hugh H. Young for his generous kindness in furnishing financial and advisory assistance and for the use of the material of the genito-urinary clinic.

ABSTRACT OF DISCUSSION

Dr. Hugh Young, Baltimore: Dr. Hinman has thoroughly studied all our pathologic records, and I think has made all of us realize that we shall have to change our text-books and do a far more radical procedure than in the past. On account of such work as Dr. Hinman's we are compelled to note a series of bad results that we did not realize were occurring.

Dr. Frederick W. Robbins, Detroit: I wondered while I listened to Dr. Hinman's paper if he had entirely forgotten the work of Coley in connection with his serum in these cases. About five or six years ago I reported a case that shows, as I believe, the result of the use of the double injection of the erysipelas and prodigiosus bacilli. A man had a very rapidly growing tumor of the testicle, probably a teratoma, although at the time I thought it was a sarcoma, which I removed without any very extensive dissection. The tumor was about as large as my fist. That the tumor was malignant I think is proved from the fact that within ten days after it was removed another growth was formed as large as my fist. I then dissected out, very carefully, the contents of the scrotum, and without opening the internal abdominal ring went up as high as I could to get everything out, and the wound looked perfectly clean. Inside of ten days the growth was again forming so that you could see it increase in size every day. I began the injection of the double bacillus. Within two days the growth had stopped and then gradually disappeared. He was under treatment about three weeks, getting a reaction at every injection. I began with a small dose and increased the dosage. The first injection caused elevation of temperature to about 103, as I remember it, but gradually it required a larger and larger injection to get a reaction, until in about two weeks the maximum dose was given. The growth entirely disappeared. The other day I heard from him, and he is reported to be perfectly well. We should not forget that there are such cases as I have had and as Coley has reported, which are wonderfully helped and probably cured by the double bacillus injection.

Dr. Edward L. Keyes, Jr., New York: In two cases I have endeavored to follow out practically the technic suggested by Dr. Hinman of clearing up the space between the ureter and the aorta as far as the kidney, and in both instances I have found the veins implicated in the disease, extending to and beyond the kidney. In one case there was a large mass of secondary glandular involvement even above the kidney, and in the other there was simply a venous involvement up to the kidney. Several other patients I have seen die from metastasis extending so rapidly after the disease once got started and of such wide distribution that it seemed to me that, taken in connection with the known fact that the veins of the pelvis and abdomen are frequently involved in the growth, the metastases occur by the vascular instead of the lymphatic route in the large majority of cases. If that is the case, I question whether an extensive dissection is going to help us revise our mortality statistics. I fancy the real thing is to get at the cases early, before vascular metastases have occurred and not to pinch the vessels when you are examining them.

Dr. M. Krotoszyner, San Francisco: In connection with Dr. Keyes' remarks, I believe that the salvation of our patients does not lie so much in the radical operation as in the early diagnosis. I do not think there is any condition in the genito-urinary tract so difficult to diagnose as enlargements of the scrotum involving the testicle. It is in these cases that the Wassermann reaction has complicated the diagnostic difficulties. Any physician who has seen many of those doubtful tumors will admit that three large conditions loom up right from the start—tuberculosis, tumor and syphilis—and he will not be willing to put the patient on the operating-table before he has at least satisfied himself that a diagnosis of syphilis can be excluded. I have seen cases in which the Wassermann was slightly or even strongly positive and in which afterwards the diagnosis of primary carcinoma of the testicle was verified pathologically. What are we going to do? In one case three months had been lost by this means, not only in my hands, but in the hands of my predecessors. I think a means ought to be established by which we are enabled as early as possible to make the diagnosis. I think then the result of our operative procedures will be better.

Dr. Frank Hinman, Baltimore: With regard to Dr. Keyes' statement concerning vascular and glandular involvement, forty-six of these cases, I think, gave a very clear indication as to the first metastasis of these tumors. In twenty-two cases the lymphatic glands were first involved at the time of operation. In eleven of these twenty-two cases the disease was so extensive as to render them inoperable. This fact, however, I think does not detract from the object of the radical operation, because four of these patients were apparently cured. An early diagnosis, of course, is the all-important thing in the treatment, but it has been shown that castration will only cure from 20 to 50 per cent. of these cases, and the radical operation, from a surgical point of view, is perfectly feasible and technically not difficult. So that in every case the lymphatic region should be explored. There certainly will be a small proportion of patients who will be cured by the radical operation who otherwise would certainly die.

"Idiopathic" Insomnia.—Insomnia is a symptom always; it is never a disease. In many text-books there is a reference to "idiopathic insomnia." That is the insomnia described by the ignorant man. We are all ignorant on this subject, and the best thing is to admit our ignorance, rather than trying to satisfy our consciences by describing it as idiopathic, or putting a long title to it or classifying it, and concluding that all is well.—H. Crichton Miller, *Medical Press and Circular.*

DIVERTICULA OF THE URINARY BLADDER

WITH REPORT OF CASES *

WILLIAM E. LOWER, M.D.
CLEVELAND

The increasing literature regarding diverticula of the urinary bladder and the frequent reports of cases which are now appearing indicate, in my opinion, not that this condition is occurring more frequently than formerly, but that it is now being more accurately diagnosed and that its treatment is now yielding more satisfactory results. Very complete reviews of the literature on this subject have been made by Fischer[1] and by Lerche,[2] who show that opinions regarding the exact etiology of diverticula still vary. Some writers believe that diverticula are always congenital while others contend that they are acquired, the point of differentiation being the presence or absence of muscular fibers in the walls of the sac forming the diverticulum. If muscular fibers be present it still is considered by many that the diverticulum is of congenital origin. If, however, the sac be formed only of mucous membrane, that is considered evidence that the diverticulum is acquired. It has been shown recently, however, that in practically all cases some muscular fibers are found in the sac wall, though they often are very much attenuated.

It seems to me, however, from the clinical aspects of the cases that have come under my observation and are here reported, that these diverticula were acquired, and the argument, which also applies for most diverticula, is: 1. They scarcely ever are found in the very young, but for the most part in persons past middle life, a time at which obstruction to urinary outlet most frequently occurs. Necropsies on children do not show this condition, or at least its presence is not mentioned in most post-mortem records. Such anomalies as hour-glass or double bladder which are occasionally reported at post-mortem findings in children are generally associated with double urethras or multiple ureters and other abnormalities and should not be considered identical with true clinical diverticula. 2. They very seldom occur in women, the ratio being about one to ten. 3. In most cases the bladder wall is much thickened, a condition present in most cases indicating obstruction to the urinary outlet, which produces more or less retention. In the one case of a woman in my own series a urethral caruncle was present which caused her so much pain that she refrained from voiding as much as possible and never completely emptied her bladder.

Even Englisch, as quoted by Fischer, believes that the so-called congenital diverticula are "based on the presence of some obstacle to the outflow of urine, in consequence of which the weak points of the muscular arrangement of the bladder give way. These obstacles may be produced by inflammatory conditions of the bladder or urethra during intra-uterine life but which have healed up, leaving no vestiges after birth."

That there probably is some congenital condition of the bladder wall which under certain conditions, such, for example, as obstruction and overdistention for a patients in whom no glands at all were found are dead. Of the six cases in which no mention is made of glands, two patients are dead, one and twelve months, respectively, after operation; three are living, one, twelve and forty-eight months, respectively, and the result in one, presumably alive, is not mentioned.

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[2] Lerche: The Surgical Treatment of Diverticula of Bladder, with Report of a Case and a New Device for Operation, Ann. Surg., 1912, lv, 285.

Obviously all cures in those patients who had cancer involvement of the lumbar glands that were removed at operation will be directly due to the radical procedure, and just as obviously the radical procedure will be able to cure in only those early cases in which the invasion has not spread beyond the primary lymph zone. Simple castration will be of no benefit in either case, and will cure in only those very early cases in which the disease is confined to the testicle proper. Of the six patients living who had glandular metastases removed, one, in whom two of the glands removed at operation showed marked invasion, is now alive and well almost five years since the removal of these glands, three other patients are alive and with no evidence of recurrence for almost three years from the time malignant lumbar glands were removed, and the two other patients were alive after operation eight and one months, respectively, at the time of the last report.

SUMMARY AND CONCLUSIONS

1. Orchidectomy will cure from 15 to 20 per cent. of teratoma testes. Obviously a cure is possible only when the testicle is removed before the onset of glandular or other metastases.

2. A cure cannot be assured until nine years after operation, although the danger of recurrence after four years is very small (only three cases reported) and progressively diminishes.

3. Cancer of the testicle metastasizes in practically every case first and primarily to a limited zone of lumbar lymph-nodes which lie on the aorta for the left testicle and on the vena cava for the right, between the bifurcation of these vessels and the renal pedicle. Communication between these two groups and to deeper or more distant glands occurs only secondarily.

4. Involvement of these primary lymph-nodes may occur early or late, and the preoperative duration of the tumor in the testicle, its rapidity of growth or its size give no definite clinical indication of the onset or extent of such metastases, but the probabilities increase the longer the duration and the more rapid the growth.

5. Pathologic differentiation of tumors of the testes into embryonal carcinomas and mixed-cell types is more or less arbitrary as both are teratomatous in origin; but the former appears to be definitely less likely to metastasize, although more rapid in its growth. There are fewer cures among the cases of teratoma, although these give the longest duration before death.

6. The primary lymph-nodes are a very imperfect guard against secondary invasion, and metastases to other gland areas by way of efferent lymph-channels or by blood-vessels to thoracic or abdominal organs may occur early. Surgical treatment is of no avail after these secondary metastases have occurred. The only hope, therefore, in a radical operation is the removal of the testicle with its primary lymph area before the disease has spread beyond this zone.

7. The experience of various surgeons in a total of forty-six cases has demonstrated in suitable cases the feasibility and technical ease of the radical operation with a combined surgical mortality in all cases of only 11 per cent.

8. Radical operation should never be undertaken when lumbar metastases are recognizable clinically, and is applicable only in the fairly early cases in which the disease is apparently limited. Owing to the deep position of the glands, these cases cannot always be differentiated before operation, so that every case, in which clinically there is no invasion, is suitable for radical treatment. The operation should never be performed until after the diagnosis is confirmed.

9. Sufficient time has not elapsed and the cases are so scattered that it has not been possible to get the ultimate result in all of the patients treated radically. Forty-six per cent. are alive, one for five years; one for four years; five for almost three years; two for over two years and eleven for one year or less. There is a probable cure in at least four cases which had lumbar glands invaded with cancer at the time of the operation. Simple castration could not have benefited any of these cases, and their cure is directly attributable to the early and clean removal of the affected lymph area.

10. In conclusion, therefore, it may be stated that the early removal of the testicle with its primary lymph zone is the rational method of surgical treatment of teratoma testes, but the extensive nature of the operation and the fact that almost one-third of the cases thus treated were found to be inoperable warrants a very careful selection of suitable cases.

I wish to acknowledge thanks to Dr. W. S. Halstead for the privilege of using the material of his surgical clinic, to Dr. J. C. Bloodgood for the valuable material of the surgical pathologic laboratory, and to Drs. Gregoire, Pringle, Chevassu, Marion and others for data in regard to cases operated on, and particularly to Dr. Hugh H. Young for his generous kindness in furnishing financial and advisory assistance and for the use of the material of the genito-urinary clinic.

ABSTRACT OF DISCUSSION

Dr. Hugh Young, Baltimore: Dr. Hinman has thoroughly studied all our pathologic records, and I think has made all of us realize that we shall have to change our text-books and do a far more radical procedure than in the past. On account of such work as Dr. Hinman's we are compelled to note a series of bad results that we did not realize were occurring.

Dr. Frederick W. Robbins, Detroit: I wondered while I listened to Dr. Hinman's paper if he had entirely forgotten the work of Coley in connection with his serum in these cases. About five or six years ago I reported a case that shows, as I believe, the result of the use of the double injection of the erysipelas and prodigiosus bacilli. A man had a very rapidly growing tumor of the testicle, probably a teratoma, although at the time I thought it was a sarcoma, which I removed without any very extensive dissection. The tumor was about as large as my fist. That the tumor was malignant I think is proved from the fact that within ten days after it was removed another growth was formed as large as my fist. I then dissected out, very carefully, the contents of the scrotum, and without opening the internal abdominal ring went up as high as I could to get everything out, and the wound looked perfectly clean. Inside of ten days the growth was again forming so that you could see it increase in size every day. I began the injection of the double bacillus. Within two days the growth had stopped and then gradually disappeared. He was under treatment about three weeks, getting a reaction at every injection. I began with a small dose and increased the dosage. The first injection caused elevation of temperature to about 103, as I remember it, but gradually it required a larger and larger injection to get a reaction, until in about two weeks the maximum removed after they had been packed tightly with gauze, while the fourth was removed by bringing the sac up through the bladder. In these three cases the convalescence was uninterrupted and in two there have been splendid functional results, but in the third there is still some residual urine which I believe to be due to a prostate which I did not completely remove at the time, although I did remove a projecting lobe which seemed to obstruct the urethra. In three out of five cases of men in each of which I particularly noted the urethral outlet there was distinct evidence of obstruction by small projecting lobes of the prostate, and in the other two the lateral lobes of the prostates were enlarged.

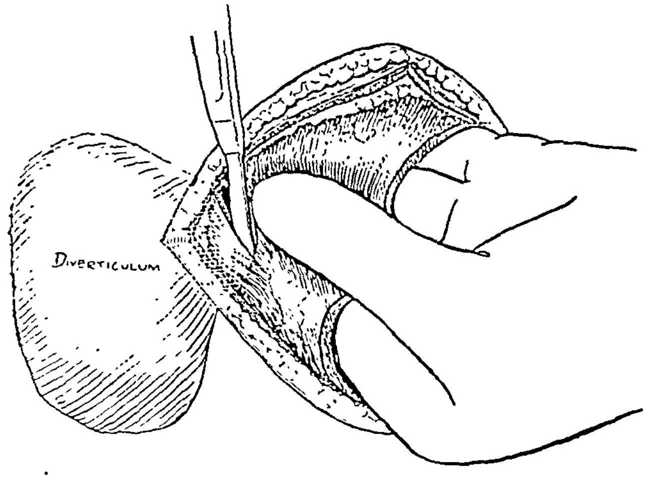

Fig. 3.—Division of the attachment of the diverticulum.

I have already referred to the case of the woman whose urethra was partially obstructed by a caruncle. In the late cases that have come under my observation I was able to determine the size and location of the diverticula by the use of collargol and roentgenoscopy. In three cases I was able to get postoperative pictures. These show the entire absence of the diverticula which are visible in the preoperative pictures.

By using collargol and the Roentgen ray for diagnosis, and by comparing the preoperative and postoperative pictures, we are able to draw very definite conclusions regarding the value of excision in these cases.

In those cases in which excision seems to be impossible, the method which has recently been suggested and so practically applied by Squier[4] is well worth a trial. He advises that a large communication be established between the bladder and the diverticulum by the use of clamps and sutures after the manner of a gastro-enterostomy.

In two cases I tried to make the diverticulum a part of the bladder cavity by dilating the orifice, but this procedure was unsuccessful in each instance as contracture followed. One patient was operated on a second time, and the other still has trouble.

TECHNIC OF OPERATION

In all the cases in which I have removed the diverticula by the method of first converting them into solid tumors, the following method was used:

1. Nitrous oxid-oxygen anesthesia with local infiltration of novocain.
2. Transverse incision through skin and fascia.
3. Infiltration of muscles. Separation of muscles and bringing the bladder up with curved forceps, and then dissecting the bladder free from the peritoneum (Fig. 1, *A* and *B*).
4. Packing the diverticula tightly (Fig. 2).

Then with the fingers inside the bladder, the index-finger in the opening of the diverticulum and the thumb on the outside, the attachment to the bladder is exposed and divided (Fig. 3).

The bladder is then retracted away from the diverticulum, traction is made on the tumor and it is dissected free from the surrounding tissue (Fig. 4).

With some of the tumors this last step was not necessary—the tumor could be brought up first and the dissection from the attachment of the bladder made secondly.

REPORT OF CASES

I wish to append herewith report of seven cases, in six of which operation was performed for the removal of the diverticula. Two other cases which I have seen are not classified herewith because I did not determine the depth or size of the diverticula, and the openings that were visible may have been but shallow depressions; but the cases cited are those which had a definite well-marked and demonstrable sac. Six of these were men and one a woman, the oldest was aged 78 and the youngest 43, average age 59. In every case there could be demonstrated an obstruction to the urethral outlet. The diverticula were single in four cases and multiple in three. The largest number in any one case was four. In one case I first did the operation of enlarging the diverticulum opening. This not giving relief, I later resected the diverticulum and drained through the perineum.

Case 1.—Man aged 49, a letter carrier, referred by Dr. Wheeland. Complaint was bladder trouble. Family history had no bearing on the case. The patient had specific urethritis when 44—five years previous. Denies any luetic infection. Two years ago began to have difficult urination. Lost 10 to 15 pounds in the last year or two. No other symptoms besides the ones mentioned above. Has catheterized himself since February, 1909.

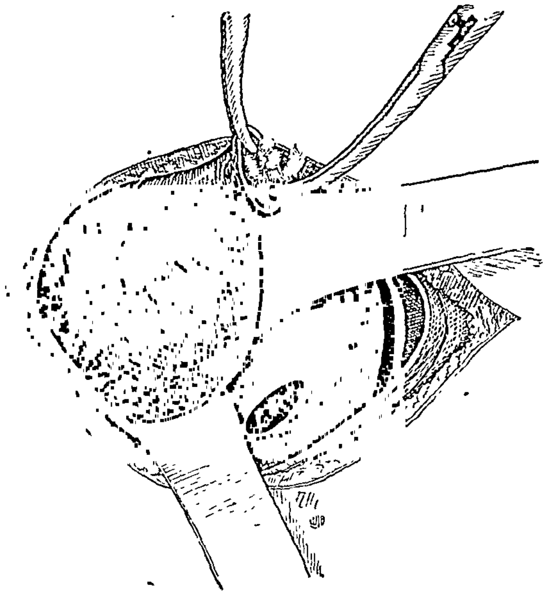

Fig. 4.—Removal of diverticulum.

Cystoscopic Examination.—Bladder capacity 300 c.c. Required many repeated irrigations in order to get the fluid

---

[4] Squier: New York Med. Jour., 1914, xcix, 1026.

Catgut was placed around the ureter after the tumor was removed and it was transplanted into the bladder through the opening from which the diverticulum had been severed. Prostate was quite large and bulged into the bladder cavity. As this was considered to be the cause of the diverticulum, prostatectomy was done. Prostate was easily removed; middle lobe was quite large. The mucous membrane over the cavity from which the prostate had been removed was pressed down with small narrow strips of gauze. Catheter allowed to remain in through the urethra, and the bladder wound left open. Small rubber cigarette drain was placed outside of the bladder in the cavity from which the diverticulum had been removed. This diverticulum was quite large.

Postoperative roentgenoscopy with collargol revealed no evidence of any former tumor. Patient made an uninterrupted recovery and has been entirely well since. Able to empty bladder easily and completely.

Case 7.—Woman, aged 74. Complaint, frequent and painful urination. Family history is unimportant. Personal history, general health only fairly good. Pneumonia at 68. For years she has had extreme annoyance during urination because of a very painful caruncle of the urethra. This had been removed, and while relieved of most of the annoyance which she previously had, she still had frequency of urination and pus in the urine. She has had autogenous vaccine treatment.

Cystoscopic Examination.—This disclosed a small opening on right side of bladder above ureter. Roentgenoscopy with collargol showed a well-defined diverticulum on right side of bladder.

Operation.—Nitrous oxid and novocain. Transverse incision; fascia divided transversely and dissected free. Muscles separated, bladder exposed and incised. Interior of the bladder exposed with a smooth flexible retractor and the opening of the diverticulum plainly seen. Through this into the diverticulum were inserted narrow strips of gauze sufficient in amount to pack the diverticulum very tightly. Then with fingers inside of the bladder and tip of the index-finger at the entrance of the diverticulum the bladder was pulled aside, the adjoining tissues dissected free and the neck of the diverticulum exposed. Without any difficulty I was able to dissect around this, bringing it up; as it was a well formed semisolid tumor now, it was easily removed from its bladder attachment. The opening in the bladder was closed with No. 00 chromicized catgut, both from within and outside the bladder.

Patient made an uninterrupted recovery and recently reported that she is entirely well. Postoperative collargol picture shows no evidence of former tumor.

1021 Prospect Avenue.

ABSTRACT OF DISCUSSION

Dr. Martin Krotoszyner, San Francisco: The diagnosis of diverticulum of the bladder may occasionally be very difficult, even in the hands of the trained cystoscopist. I recently observed a man of 57 who entered the hospital with a severe pyuria which I at first interpreted to be due to involvement of the so-called middle lobe of the prostate. For two or three weeks it was impossible to obtain a clear picture of the bladder, in spite of repeated cystoscopic sittings, on account of the fact that invariably the almost clear bladder fluid suddenly became cloudy. I suspected the pyuria to be due to a pyonephrotic focus until this suspicion was removed by successful bilateral ureteral catheterization. Finally, after a great deal of laborious work, it was possible to clear up the bladder to such an extent that a large diverticulum could be seen, situated about 1 or 2 cm. below and to the left of the right ureter.

Dr. George Smith, Boston: Has Dr. Lower had any of these cases which have not shown much residual urine? Has he met any diverticula in which the mouth was so small that the contents would not come out on catheterizing the bladder?

Dr. William E. Lower, Cleveland: In reply to the question of Dr. Smith, in only one case was the orifice so small and the muscular contraction about the opening so strong that the contents could not be emptied by catheterization. This is a condition that must be borne in mind, and especially if we depend on the amount of residual urine as a diagnostic factor.

ACUTE PARENCHYMATOUS GLOSSITIS *

VIRGIL LOEB, A.B., M.D., D.D.S.

ST. LOUIS

The basis of this paper is a case of acute parenchymatous glossitis which I reported superficially in a paper entitled "Unusual Cases in Oral Surgery," read before the St. Louis Dental Society during May, 1911.

In connection with the detailed report of the case which I now propose to give, I desire to enter into a brief discussion of the disease and the literature relating to it. Butlin, in his book on "Diseases of the Tongue" says:

> Acute inflammation of the tongue is admitted by all observers to be a rare disease. Even the largest hospitals in this country [England] do not, in most years, record a single instance. Yet the history of the disease may be written with tolerable accuracy, for the very rarity of acute glossitis has led to the publication of a goodly number of cases in medical literature.

From the reports of cases which I have been able to review, acute parenchymatous glossitis has been spoken of as acute glossitis, idiopathic glossitis, phlegmonous glossitis, deep glossitis and interstitial glossitis.

Baldwin[1] describes a case which he had observed, under the title "Interstitial Glossitis," and Wagner[2] reports a case using the term "Idiopathic Glossitis." Saenz[3] and Dupérier[4] each speak of the disease as *Glossité profonde* rather than as *Glossité parenchymateuse.*

The disease is noticed most often during the winter months and attacks males more frequently than females. It occurs chiefly between the ages of 20 and 40, though Bennett,[5] in reporting a study of the literature from 1816 to 1906, states that cases have been reported at 9 months and 80 years of age.

Among the etiologic factors relating to acute parenchymatous glossitis, exposure to cold and dampness together with a lowered general resistance seem to be the most potent. Infectious diseases also play an important rôle. Weis[6] described a case which followed the desquamation of scarlet fever. Sabrazes, Bonnes and Parsat[7] report a case in a man whose children had had scarlatina just previous to his illness and they thought the patient may have had a scarlatinal throat. No specific germ has been isolated, though streptococci and staphylococci have been found.

Predisposing causes are injuries to the tongue from carious teeth, faulty dental work, tooth-picks, splinters of wood and other foreign bodies. Gerhard[8] adds as further causes the action of corrosive substances, hot liquids and the stings of insects.

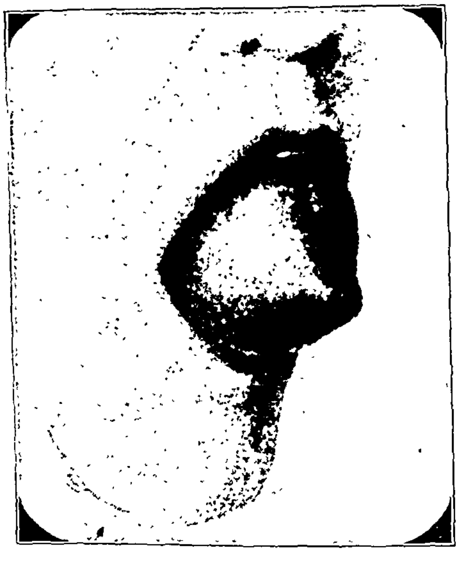
Sore throat often precedes an attack as in cases described by Washburn[9] and Green.[10]

The disease is usually ushered in by pain which is located in the tongue but often in no specific area. This pain comes on suddenly and increases gradually in severity. Accompanying it, though not always immediately, there develops a swelling of the tongue which increases rapidly until the organ fills the entire oral cavity, and often protrudes outside the mouth. In some cases designated as hemiglossitis, the swelling is limited to one side, usually the left. Bennett[5] found from a study of 145 cases that in 85 the entire tongue was involved. In 36 the glossitis was limited to one-half of the tongue, and of this number 20 cases were on the left side. Thomas[11] reports one case of hemiglossitis and Duckworth[12] and Copland[13] each report four. In the majority of these the left side was involved. Coincident with the swelling there is a rise of temperature with a corresponding pulse and salivation. The tongue is covered with a dark brownish fur on the dorsum and is tense, dry and hot. Deglutition is impossible and breathing very difficult. There is extreme discomfort and the facial expression is one of great anxiety. The cervical glands are usually palpable.



Dr. Loeb's case of acute parenchymatous glossitis.

Butlin[14] says the diagnosis of acute parenchymatous glossitis "is generally so easy that it seems almost unnecessary to speak of it." He states, however, that it is at times difficult to differentiate from acute edematous swelling due to salivary calculus and other affections of the floor of the mouth. Bennett adds acute ranula and herpes of the mouth, lips, tongue or pharynx as diseases from which it should be diagnosticated.

The pathology is simply that of an acute violent inflammation. Thebaud[15] says there is a violent injection and swelling of the lymph-vessels chiefly in the muscular structure of the tongue.

The prognosis of acute parenchymatous glossitis should be guarded, on account of the complications which may arise in all cases. Bennett, however, states that of 145 cases which he reviewed, only four ended fatally or less than 3 per cent. Recovery may be by resolution, or suppuration may develop. In some cases gangrene takes place, which renders the outcome very grave.

The treatment should be immediate and surgical. Deep longitude incisions along the dorsum of the tongue on either side of the median line seem to be generally accepted as the best procedure. Sonbeyrau[16] recommends a median incision.

Saenz[3] after a study of eight cases, states that since glossitis often ends spontaneously, it is prudent to await this, provided no alarming complications develop. Dupérier[1] also reports eight cases, but recommends immediate deep longitudinal incisions.

If suppuration has developed, free drainage must be obtained. Thebaud[15] reports seventeen cases and in his conclusion states that when a deep abscess develops at the base of the tongue which cannot be reached by the oral route the same must be attacked from without.

In cases which develop gangrene, cauterization should be used. In addition to the purely surgical treatment, antiseptic mouth-washes should be used freely, together with constant cold applications to the tongue. Pain should be allayed by the use of morphin, etc.

REPORT OF CASE

Patient W. O. A., white, married, aged 50, traveling salesman by occupation, consulted me first Nov. 9, 1910. Patient gave the following history:

Eleven days ago while in the South he began to notice pain in his tongue. He could locate it at no definite point but said it seemed to be in the substance of the organ. The only cause which he could give was that he was in the habit of whittling pine sticks and sticking the splinters in his mouth. He thought he had scratched the under surface of his tongue with one of these splinters. He also had been chewing some fresh perique tobacco. The pain became steadily more intense, especially on the right side, and was more noticeable when swallowing. He remained in the South for several days under treatment, but obtained no relief.

The patient was a well-built, robust man, color good, with facial appearance one of extreme uneasiness. Physical examination, negative. Personal history, negative. Denied syphilis.

Examination of his mouth revealed a somewhat inflamed mucous membrane and several carious teeth. The tongue was apparently not swollen, nor was it especially inflamed. There was a small abrasion which was healing on the right side, but otherwise it was apparently normal. One gland in the right anterior cervical region was slightly enlarged. Temperature normal. The patient was extremely nervous. He said he had taken practically no nourishment for three days. On pressure over the right side of the tongue, far back near the base, the patient complained of excruciating pain.

The patient was sent to a hospital and cold applications to the throat and tongue ordered. Aspirin, 5 grains, was given every three hours. That night the patient slept fairly well and felt somewhat relieved the following morning. An examination of his urine at that time showed some albumin, hyaline and granular casts and a few pus cells.

The relief which the patient had had continued only until the afternoon of the second day in the hospital, November 10. The pain then returned in increased severity. Large doses of aspirin were given and veronal in 5-grain doses, with little relief.

November 12, for the first time, a slight edema around the orifice of the right Wharton duct was noticed. There was still no swelling of the tongue. That afternoon a neurologic examination was made by Dr. S. I. Schwab, but nothing which might be responsible for the pain was found.

By November 13, a most spectacular change had taken place in the tongue. It had become swollen until it prac-

tically filled the entire mouth cavity. It protruded from the mouth, was very dry and hot. Temperature 100 F. The patient was semiconscious, breathing very heavily. Nourishment was given by nasal tube and water by rectum. A blood-count was made showing 12,478 leukocytes. Urine examination showed a large amount of albumin, hyaline and granular casts and a few blood and pus cells.

A consultation was held with Dr. P. Y. Tupper and an immediate operation determined on.

After anesthetizing the tongue with local applications of cocain, I introduced an aspirating needle for the purpose of determining whether or not an abscess was present, and also for the purpose of reducing the pressure by local bleeding. I aspirated ten times in as many different places, and at different depths, but found no pus present. The bleeding was profuse. The patient was put to bed and continuous ice-cold irrigation was applied to the tongue. Nasal and rectal feeding were continued.

Patient had a most uncomfortable night, with severe pain, which was relieved only by a large dose of morphin. Patient felt better by morning. From this time he began to improve. The temperature rose to 101, dropping gradually, and except for acute exacerbations of short duration the pain became less intense. Within four days the tongue had become reduced to such a size that the patient could talk fairly audibly and could swallow without great discomfort. Most of the pain from now on was due to ulcerations on either side of the tongue, caused by pressure against lower right and left carious molars.

From this time until the patient left the hospital, a period of two weeks, the treatment consisted of cold applications to the tongue and applications of argyrol in 25 per cent. solution, to the ulcerated areas. After leaving the hospital the patient gained strength rapidly and on Jan. 3, 1911, was pronounced entirely well. He was treated by Dr. J. S. Myer for his acute nephritis, from which he also recovered.

537 North Grand Avenue.

ABSTRACT OF DISCUSSION

Dr. Gordon New, Rochester, Minn.: About three weeks ago I saw a case almost as extensive as this, following an abscess at the root of a third molar tooth. The patient recovered, however, after drainage in the submaxillary region. Other than this I believe there is nothing to record about the case.

Dr. F. B. Moorehead, Chicago: It is difficult at times, if not impossible, to make a differential diagnosis between parenchymatous and interstitial inflammatory conditions excepting, of course, microscopically. A boy of 17 was sent to us with a history of acute abscess from the lower incisor tooth. The tooth had been extracted some ten days previously, and following the extraction an extensive swelling had developed, more in the floor of the mouth than in the tongue, which had the appearance of a typical Ludwig's angina. The swelling went backward and the patient had difficulty in swallowing; the tongue began to enlarge and completely filled the mouth. The swelling in the lower part of the mouth and tongue made tracheotomy necessary. The pain was very severe, temperature 102.

Dr. Theodore Blum, New York: What was the infection from which this came?

Dr. Moorehead: A simple alveolar abscess, I imagine. I did not see the case until the original focus had cleared up, the patient coming to me with a mass of induration on the floor of the mouth.

Dr. Blum: Was a roentgenogram taken?

Dr. Moorehead: Yes, but it showed nothing except the empty socket from which the tooth had been removed. There was no other bone involvement.

Dr. M. I. Schamberg, New York: The cases of glossitis that we come in contact with are usually secondary to other disturbances, as stated by Dr. Moorehead. The description of the case which Dr. Moorehead has given us is identical with a case which recently came under my care, in which the suppurative site was in the submaxillary region and had extended to the tongue, so that the tongue showed a certain amount of the extension of the inflammation. Another patient was sent to me as a case of glossitis showing evidence of swelling in the tongue in which the physician in charge suspected a specific origin. The history of the case as obtained from the patient showed no history of an initial lesion. The patient was married, his wife had borne several children and there had been no miscarriages. On examination I determined, with some difficulty, a slight ulcerated spot on the lateral aspect of the tongue in relation with two or three molar teeth. This they attempted to explain because of the swollen tongue coming in contact with roughened teeth. I was, however, suspicious that the case was malignant and took a fairly good section from that portion of the tongue and sent it to one of the best pathologists in New York. The report came back that it was not malignant. In spite of this I persisted in the view that it was malignant and that we had not reached the tissue showing the typical pathologic changes. The case passed out of my hands at that time because the physician called in some one else for a Wassermann. A positive Wassermann was found and the case was treated with salvarsan. There was an improvement, and I was also informed subsequently that the lesion that was removed from the tongue was malignant. It is important in these carcinomas of the tongue to remember that they are often deep seated and that the removal of superficial tissue will not determine it. I thought I had gone well into this ulcerated region and that I had obtained some of the involved tissue, but the diagnosis was made absolute by the pathologic finding after the removal of the tongue.

These tongue cases are exceedingly malignant and the only salvation is to see them as early as possible. In another case there was a slight ulceration on the side of the tongue which attracted attention. The patient was sent to a physician who diagnosed it as an initial lesion of syphilis and treated the patient for chancre. When the patient came to me the tongue was well indurated beyond the median line. I advocated the removal of the tongue, but the patient would not consent to the operation and went to an untimely death six months later. The only chance in these cases is to make an early diagnosis and they should be looked on with grave suspicion, particularly cases of glossitis that do not show suppurative lesions or in which the blood-count does not indicate the presence of disease in the system.

Dr. A. H. Levings, Milwaukee, Wis: So far as my experience goes, practically all of these cases are due to infection. It may be either streptococcic or staphylococcic. The point of infection we may not be able to determine, but it is usually some scratch or abrasion as from a roughened tooth, or it may be the sting of an insect. I have never seen a case of parenchymatous glossitis that I thought I could not differentiate from carcinoma. Dr. Loeb's treatment of the case I think was excellent; either make numerous punctures or make a free incision, the idea being to deplete the tissues, cause free hemorrhage, and get rid of the infection.

Dr. Virgil Loeb, St. Louis: I had intended to make a deep incision, but finding no pus present and getting satisfactory results by aspiration, there was no occasion for such a procedure. In differentiating from any malignant disease of the tongue, I examined the patient thoroughly before the swelling developed and there was no sign of induration.

Public Health and Personal Hygiene.—Public health is made up of units, personal health is public health, personal hygiene is public hygiene. If perfect health on the part of the farmer is considered, he will not allow milk to be dirty, allow pollution to get into the well or brook or stream. If you are working for public health you are working for personal hygiene, individual, clean, sanitary living and if each individual would follow that out public-health problems would be largely solved. Health doctors to be successful must expect to train the individuals they come in contact with in the laws of personal hygiene.—W. H. Sawyer, *Journal Michigan State Medical Society.*

A STUDY OF THE BACTERIOLOGY OF ALVEOLAR ABSCESS AND INFECTED ROOT CANALS*

THOMAS L. GILMER, M.D., and A. M. MOODY
CHICAGO

Since Billings, Rosenow and other internists have found the mouth a prolific primary focus of infection, fraught with secondary manifestations of grave consequence, it has been thought desirable that a closer study of the bacteriology of alveolar abscess, both acute and chronic, as well as the infectious material found in pulp chambers and root canals, should be made.

The impression generally entertained that alveolar abscess, both acute and chronic, is due to the *Staphylococcus albus* and *aureus,* seems from our study not well founded. We have received this accredited opinion, not from written statements, but from questions put to those whom we knew had had such experience in the observation and treatment of alveolar abscess, and their answers have been expressed as before indicated.

One looks in vain for statements in books which treat of alveolar abscess of opinions on the bacteriology of this disease. The subject has been thought either of too small consequence to warrant discussion, or too difficult of solution. We recognize that abscesses of the jaws are by no means the only mouth conditions to which joint, heart and other lesions may be attributed, but we have made our study of the bacteriology of tooth infections partly because so little attention has been given it and because we were able to gather from such foci specimens with less liability of contamination, than from pyorrhea alveolaris pockets, for instance. The mouth, even in health, affords a great flora, both of pathogenic and non-pathogenic bacteria, therefore great care and painstaking was necessary in the collection of material which would be uncontaminated.

In gathering specimens from acute alveolar abscess the field to be incised was made as nearly aseptic as possible by thorough washing with 50 per cent. alcohol, and as soon as the incision was made a sterile pipet was introduced deeply into the abscess and the pus collected. The pipet was then sealed and sent to the laboratory.

In the chronic infections, abscesses without sinuses were selected and similar precautions observed for the collection of specimens. In others, the pus was collected direct from the pulp canals of teeth having *no* cavities of decay; the tooth being thoroughly washed with alcohol after the application of the rubber dam, then drilled through into the pulp chamber with a drill, and as the pus welled up from the canals it was received in the pipet. In others, the pus was collected from the apices of freshly extracted teeth which had been removed under careful aseptic precautions. The specimens from septic root-canals were gathered from teeth recently removed. In order to expose the root-canals the teeth were enveloped in sterile gauze and placed between the jaws of a vise and crushed, others were flamed and the roots then split with sterile bone-cutting forceps. These methods exposed the pulp-chambers and root-canals from which the specimens were obtained. In some of the teeth thus examined there was found pulp-tissue partly gangrenous and partly alive, in others only necrotic elements of the pulp, the pulps in some having been dead for a long period of time, as indicated by the presence of old imperfect root-canal fillings.

The presence of bacteria of various kinds within the structures of the teeth and the tissues adjacent to them was demonstrated many years ago by Miller (Micro-organisms of the Human Mouth) and others. From our work it would seem that we are now able to classify the more important organisms which correspond in many respects to descriptions and photomicrographs of bacteria of the dental structures appearing in the literature as early as 1881. Our conclusions are arrived at from some forty odd bacteriologic examinations, which it has been our privilege to make of material from acute, subacute and chronic or latent infections of the jaw and teeth. There were sixteen acute alveolar abscesses, eighteen subacute or chronic abscesses and eight teeth with diseased root-canals from which material was received for bacteriologic examination.

In the main there has been a great similarity in the results obtained. We believe that to obtain such constant results as we have, the same technic should be employed. That technic is the following:

After receiving the material to be examined, collected in the manner described above, it is smeared on the surface of blood-agar or ascites-dextrose-agar slants. One tube is placed under anaerobic conditions by the addition of pyrogallic acid and a few drops of sodium hydroxid to the tube after the cotton plug has been pushed in about one-third the distance from the top. The tube is then plugged with a plain cork and sealed with paraffin. The other inoculated tube is kept under aerobic conditions and both are placed in the incubator at 37 C. (98.6 F.).

Within twenty-four hours one will usually see a fine granular growth over the surface of the aerobic blood-agar slant. If one examines this closer the growth is seen as fine greenish colonies. The water of condensation contains chains of these organisms which are usually Gram-positive. There may also be a similar growth in the anaerobic tube but one cannot distinguish the green color. At the end of forty-eight hours, however, there is quite a change in the appearance of the anaerobic growth; it is very luxuriant, grayish-white in color and the colonies have a great tendency to fuse. On opening this tube one notices immediately a very offensive odor.

The above hurried gross description of the cultures will hold for the great majority of the specimens from the chronic infections examined. The variations are due to the predominance of one or other of the principal organisms present, and to whether or not the material cultured has been contaminated with unimportant bacteria from the mouth. The bacteriologic results in our series of acute abscesses differed mainly in the aerobic findings. In these there were varying degrees of hemolysis of the blood.

From the microscopic examination for further identification of the organisms in question, we found the predominating organism to be a streptococcus. We have obtained many graded variations from a hemolytic streptococcus with a wide zone of hemolysis in the acute abscesses, to a *Streptococcus viridans* in the chronic, and just recently one in which a *Streptococcus mucosus* was the predominating organism. These organisms, particularly the green-producing streptococci will in many instances grow as well anaerobically as they will aerobically.

---

* Read before the Section on Stomatology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

* From the Laboratory of St. Luke's Hospital.

The anaerobic cultures which do contain streptococci are rarely pure. Some contain *Bacillus fusiformis* in varying numbers. A few of these tubes, however, have practically pure cultures of fusiform bacilli.

The above results are what we have learned to expect, but there are many other organisms which occur with these. Aerobically we occasionally obtained isolated colonies of *Staphylococcus aureus* or *albus, Micrococcus catarrhalis,* and some unidentified saprophytic organisms. In two instances a diphtheroid bacillus has been found which grows under both aerobic and anaerobic conditions.

Anaerobically, in old cultures, we have seen in material from three different abscesses a black pigment-producing organism. This organism is slow growing and does not usually appear for about five days. We do not believe that it is of any importance in these infections.

In three of the chronic cases from which material was examined the patients were treated with autogenous vaccines with strikingly beneficial results. The vaccines were made from the cultures of both the aerobic and anaerobic organisms, and were given in graded doses at five-day intervals.

These were chronic suppurations, following that class of acute infections of the mandible characterized by much brawny swelling, persisting over a week or more with little or no indications of pointing. The pus discharge continued with no seeming diminution for several weeks after the acute symptoms had subsided. In each instance the pus flow stopped promptly on the use of the vaccine treatment.

Those who have made extensive observations of the tendency of acute attacks of alveolar abscess recognize that they occur epidemically. Whether the epidemics of streptococcus nose and throat infections follow or occur simultaneously with epidemics of alveolar abscess is a question both of interest and importance. We have not sufficient data to warrant a definite statement relative to the subject, however, since we have found in both infections the same bacteria; and as both occur epidemically it may be discovered that there is a very definite relationship between the two infections.

It seems reasonable to suppose that the presence of the streptococcus of nose and throat infections may easily cause simultaneous or secondary infections in the jaws, the organisms reaching the apices of the roots through cavities of decay in the teeth, or through the circulatory channels.

Since the discovery of a positive relationship between tonsil infections and secondary manifestations in other organs and parts, tonsils have been removed wholesale, in some instances on slight provocation. Their removal has, we fear, become with some almost a fad. A similar fad is growing up relative to the removal of teeth, since the discovery that jaw abscesses and pyorrhea alveolaris are equally as potent foci for secondary infections as are the tonsils. Some physicians are rather indiscriminately sending their patients to the extraction specialist, requiring removal of several or all of the teeth, supposing them to be a factor in some lesion, when their removal is not always justified. A roentgenogram, if properly made, is infallible, and can be absolutely relied on providing its interpretation is correct, but an improper exposure may lead one, if inexperienced, to mistake a part of the maxillary sinus for an abscess at the end of the roots of the second bicuspid or first molar. Other errors from incorrect readings may lead to similar wrong conclusions.

Some jaw abscesses may be cured by treatment through the tooth's root, still others by surgical interference, other than by extraction. Pus appearing at the free margins of the gums does not always indicate the so-called pyorrhea alveolaris. It may be due to lime deposits, the removal of which permits a speedy return of the gums to health. The diagnosis of this class of pathologic conditions of the mouth requires special study and an educated technic.

People's Gas Building—St. Luke's Hospital.

MOUTH INFECTION AS A SOURCE OF SYSTEMIC DISEASE *

FRANK BILLINGS, M.D.
CHICAGO

The subject assigned is "Mouth Infection as a Source of Systemic Disease." I shall confine my remarks to infection of the jaws (alveolar infection) as related to systemic disease. Many radiographic films of the jaws have been made from patients in our clinic at Rush Medical College and the Presbyterian Hospital suffering from chronic arthritis. One film shows an alveolar abscess occurring in a patient with Hodgkin's disease. These films as a means of recognition of alveolar infection are not new to members of this section, but this method of examination of alveolar disease is not sufficiently utilized by dentists and physicians generally. It should be used, for by no other method may one know the exact condition of the alveoli and roots of the teeth. Alveolar infection and abscesses may be primary and due to unhygienic conditions of the mouth and I am sure it is often intensified and prolonged by irrational dentistry—teeth with infected pulp crowned or improperly filled. General malnutrition (scurvy, etc.) may cause mouth infection and alveolar disease. But whether primary or secondary, alveolar focal infection may be the dominant factor in the production of systemic disease, of which malignant endocarditis (*Streptococcus viridans*), chronic arthritis and myositis are examples. From the infected alveoli and tooth canals we have made bacterial cultures. The dominant organisms belong to the streptococcus-pneumococcus group. I would refer you to the brilliant results of the investigation of our colaborer, Dr. E. C. Rosenow, on the mutation of cultural and pathogenic characteristics of this group of bacteria. In addition staphylococci, a fusiform bacillus, the *Bacillus aerogenes capsulatus,* and various saprophytic organisms are found. The streptococcus-pneumococcus group apparently comprise the important pathogenic bacteria related to systemic disease. In five patients suffering from Hodgkin's disease, an alveolar abscess has culturally yielded the diphtheroid bacillus, which is found in the enlarged lymph-glands in that disease. We also know that systemic actinomycosis may arise from alveolar infection due to the ray fungus.

---

* Address before the Section on Stomatology, American Medical Association, Atlantic City, June 24, 1914, in a symposium on Mouth Infection.

Systemic disease due to a focus of infection anywhere, is probably always hematogenous. The study of the infected tissues of experimentally inoculated animals and the infected muscles, joint tissues, lymph-nodes proximal to infected joints, nodes on tendons, etc., of patients, yield specific bacteria, and histologically there is found embolism of the small and terminal blood-vessels. Local hemorrhage and endo-arterial proliferation result in interstitial overgrowth, cartilaginous, osseous, vegetative and other morbid anatomical changes, dependent on the character of the tissue infected.

Partial or complete ischemia of the tissues due to the embolism is an important factor in the production of the morbid anatomic changes. Oxhausen of Berlin has produced, in animals, aseptic osteochondritis resembling arthritis deformans, by ligating the arteries supplying the joint tissues. These principles are, I think, susceptible of proof, that a chronic alveolar infection, and chronic foci in other regions also, may cause systemic disease by hematogenous bacterial emboli, which infect and at the same time deprive the tissues of nourishment. Local infection of muscles, joint tissues, etc., and lessened blood-supply result in the peculiar morbid anatomy of the respective tissues.

To investigate and manage these patients requires team work of the clinical and laboratory workers. The clinician must carefully examine the patient, exhausting every detail in the personal history. The skill of the dentist, the nose and throat specialist, the gynecologist, the genito-urinary expert and others may be necessary to locate the foci of infection. The focus must be destroyed. Tissues and exudates of foci should be carefully examined and bacterial cultures made. Vaccines of the dominant bacteria may be made for subsequent use.

With the source of the infection removed, the attempt should be made to increase the defenses of the body against the systemic infection. This involves a long and tedious period in the chronic joint infections and also in some other systemic diseases of focal origin. Rest, both mental and physical, is essential. Good, wholesome food, pure air, optimistic surroundings and, if necessary, restorative tonics of iron and other drugs. Pain must be palliated by simple drugs like the salicylates. After a time passive exercise and later active graduated exercise must be followed to aid in the restoration of local circulation and to hasten restoration of the morbid changes of the tissues. Autogenous vaccines may be used in the attempt to improve the defenses of the body. In chronic arthritis, with the circulation of the infected tissues obstructed embolically, antibodies in the blood stream, even if augmented by vaccines, would have but little effect locally. In the later stages of chronic arthritis when the local circulation has been so improved that the tissues are flooded with blood, vaccines will be of undoubted value. Patients may, however, be cured of chronic arthritis by the other measures named without the use of vaccines.

To recognize the character of this class of systemic disease and to manage successfully the patient, the physician must have absolute control. This implies hospital care where team work of the staff may insure qualified clinical and laboratory workers.

MOUTH INFECTION AS A SOURCE OF SYSTEMIC DISEASE *

C. H. MAYO, M.D.
ROCHESTER, MINN.

It has taken a long time for the general public to appreciate the full rôle of infection in the production of death, while even in the medical profession, more has come from the study of infections in the prevention of disease than in increasing the means of cure of disease, great as have been the results of treatment.

Since all animal life depends on some other form of cell life, vegetable or animal, it seems but the part of all life to carry on this process of germinative development and maturity. It is only the resistance of healthy cells that prevents the inroads of the myriads of ever-present bacteria and animal parasites which are striving to get a foothold that they may in turn carry on their life work. Disease, then, is an inflammatory process from infection and the efforts at repair. It may also be chronic from the failure of cell life through lack of defense, from defective nutrition and advancing age.

We still speak more or less lightly of the so-called diseases of childhood, and the time is not far past when mothers took their children to be exposed to whooping cough, mumps, etc. To-day the intelligent woman knows that it is not necessary that the vitality of the child should be jeopardized by such preventable diseases, and that when they occur it is through carelessness, neglect or ignorance on the part of some one.

A comparatively small number of infections occur through wounds of the cutaneous surface. Many of those affecting the special organs are incurred through direct or indirect contact, as those of the eye and of the genito-urinary system. They may make most serious inroads on the general health. Infections which produce the greatest number of diseases enter the system by way of the alimentary and respiratory tracts. Somewhere in the line, then, of the alimentary and respiratory tracts and in the excretory ducts of the body lie the sources of the entrance of organisms which terminate life in the majority of instances. The great importance of the well-known diseases of the nasal passages with their sinuses, the lymphoid tissue of the pharynx, including the tonsils, and the diseases of gums and teeth, which have been given prominence by the dental profession during the last three years, is now more generally appreciated.

The mouth is the harbor of many varieties of bacteria which are constantly taken into the stomach during the process of eating. We have long looked on the acids of the stomach as destructive to such bacteria, but Smithies, in a microscopic examination of gastric extracts from 2,406 different individuals with "stomach complaint" (dyspepsia, indigestion and the like), showed that irrespective of the degree of acidity of such gastric extracts, bacteria were present in 87 per cent. Morphologically cocci and diplococci were present in 83 per cent.; short and long rods (often of the colon group) in 58 per cent.; typical streptococci and staphylococci in 17 per cent. and *Leptothrix buccalis* in 24 per cent. In fifty-four cultural studies of saliva from "dyspeptic" patients, streptococci and staphylococci were demonstrated in over 80 per cent., bacilli in 66 per cent. and *Leptothrix*

---

* Address before the Section on Stomatology, American Medical Association, Atlantic City, June 24, 1914, in a symposium on Mouth Infection.

buccalis in more than 14 per cent. Comparing these figures, it would appear that the common forms of pus-producing organisms (streptococci and staphylococci) have their proliferation retarded in gastric juice, but that bacilli (often of the colon group) as well as *Leptothrix buccalis* thrive in the stomach.

Bacteria of various forms live in the small intestine, or at least pass through it or into the blood stream by way of the mucous membrane. They exist in such great numbers in the large bowel that, whether living or dead, they constitute a considerable bulk of the dejecta. During the last few years some important points have been added to our knowledge of bacteria. Living germ life in the blood, or bacteremia, occurs in all infectious diseases. According to their number and virulence, the blood responds in slight or extreme degree to the symptoms, general and local, constituting the disease.

We have long known that bacteria were specified in type and action in all diseases in which we have been able to identify a specific germ. Rosenow has done a great work in showing that changes in environment may so change bacteria that specific action varies. The appearance of the bacteria is also unlike that of the original cell. In the blood stream these various forms, once they enter it, are selective in choosing their location, thereby developing specific local disease. The old "idiopathic" osteomyelitis of the child we now know may follow a short time after a specific tonsillitis. Pyorrhea, tonsillitis or sinus disease may be the source of an infection which we call rheumatism. Root abscesses and pus pockets connecting with them are often the source of acute and chronic rheumatism. The nasal sinuses and chronic mouth and throat infections develop anaphylaxis from the constant poisoning, and their results are shown in hay fevers, asthmas, urticarias, etc. Rosenow's work is going far to show that ulcerations of the stomach are conditions in which the mucosa is attacked from behind through the blood stream by bacteria which live in the blood and have a selective affinity for these particular areas. Septic bile which, in the majority of instances, is caused by infection is carried to the liver through the portal circulation. It creates such changes in the bile that it fails to activate the pancreatic and duodenal secretion, thus making various phases of indigestion, with qualitative rather than quantitative food trouble. Lower down we have the appendix with its lymphoid tissue which approximates in character that of the tonsil. Here the acid types of bacteria have the same opportunity, could they but enter the blood stream, of making erosions of the gastric mucosa as the specific form which is found in the mouth. We may here note that acid-secreting or acid-bathed surfaces are very subject to cancerous change, while alkaline-bathed surfaces are much less liable to be involved. Saliva is neutral or slightly alkaline in health, yet less than 20 per cent. of people have healthy mouths. The infected mouth shows a tendency to the acid reaction and it is through this acid change that we have an additional danger in cell degeneration, of malignant type, from chronic irritation.

The stomach is the most common location of all cancers, while the alkaline small intestine is rarely subject to cancer and the duodenum is most resistant to it. The large bowel again reverts to an acid reaction and is very subject to cancer. So also is the bladder. These structures with acid secretion are of more recent development than are many tissues of animal life, several of them being classed as organs of convenience, which fact renders them possibly less resistant.

Certainly enough is known concerning infections and their mode of entrance, that the infected and diseased mouth and respiratory tract must be looked on as most serious menaces. Much may be done by more general and effective school inspection. The present generation of children will understand and demand protection for their children in time. The first teeth should be watched, that the second be not permitted to erupt irregularly, causing deformities. Jaws should be spread that the teeth may meet and the high arched palate, diminishing nasal breathing, thereby reduced. Tonsils and adenoids should be looked after, thus preventing ear and mastoid diseases, rheumatism, endocarditis, etc. In chronic and recurring diseases, a search must be made to establish positively the nonparticipation of each of the several sources of infection.

The physicians engaged in this line of observation require fully as much training in the rudiments of dentistry as the dentist does in the signs of infectious diseases. While we have leaders in all professions, through the energy of their kinetic glands, the big stick which leads to our advancement is in the hands of the progressive and educated public who are constantly demanding more of their dentists, of the medical profession, and of the state in protecting them against preventable diseases.

MOUTH INFECTION AS A SOURCE OF SYSTEMIC DISEASE *

E. C. ROSENOW, M.D.

CHICAGO

Cultures from emulsified tissues in various systemic disorders, such as the adjacent lymphatic glands draining the involved joints in arthritis deformans, in acute articular rheumatism, and the lymph-glands in Hodgkin's disease, have yielded interesting results. One striking thing in connection with some of the more chronic infections is that the character of the micro-organisms found in the lesion may be quite different from the character of the micro-organisms in the focus of infection at the same time. This, however, does not minimize the importance of the focus of infection in any way. The organisms found in the tissues may have undergone change. This fact should be borne in mind whenever autogenous vaccines are to be used. The poor results in some cases of arthritis, for example, following the use of autogenous vaccines prepared from the tonsils or other presumable focus, may be due to the fact that the organisms present in the focus at the particular time when the cultures were made were not like those actually infecting the tissues. And if so, the vaccine would fail to contain the proper antigen.

While the most common location of the focus in various infections is probably in the head, and hence the great opportunity for you, it may be located elsewhere. Thus in two cases of typical rheumatism we succeeded in isolating the *Streptococcus rheumaticus* from the stool; in one from an infected ingrowing toe-nail, and in another case from the wound in the thumb following a crushing injury.

---

* Address before Section on Stomatology, American Medical Association, Atlantic City, June 24, 1914, in a symposium on Mouth Infection.

The abscesses or bony changes found about the roots of teeth in various systemic diseases, especially in cases of chronic arthritis, may or may not be primary, but if found the condition should be corrected, because vaccine or other treatment largely fails so long as there exists an active focus of infection, as shown, particularly by Billings. My study on the effect of varying degrees of oxygen tension on the members of the streptococcus group, together with other facts, makes it likely that it is in the focus of infection that changes in virulence occur and the different affinities for various structures are acquired. In other words, the focus of infection is to be looked on not only as the place of entrance of the bacteria, but also the place where the organisms acquire the peculiar property necessary to infect. In the light of our present knowledge the argument that infections in the mouth are so common in individuals in apparent health, does not minimize their importance. These or other foci are so common in patients suffering from arthritis, neuritis, appendicitis, ulcer of the stomach and cholecystitis, goiter, etc., and so rare in individuals who have had superb health for years, that their direct etiologic rôle can scarcely be questioned.

Regarding autogenous vaccines, our ideas need to be revised somewhat in view of the fact that the vaccines administered are usually prepared from streptococci in the focus and which may or may not be the causative organism. The instances in which good results are obtained are probably those in which the focus harbored the causative organism and the vaccine prepared from it. The instances in which poor results are obtained may be due to the fact that the vaccine does not contain the proper antigen.

With regard to the foci: What are they, where are they, and what organisms are usually present? Probably the most common location of the focus or source of infection is the mouth. The tooth socket has a structure similar to that of the joints, and a blind abscess at the apex of a tooth may have no more significance than the lesion in the joint. While it is proper to remove the teeth that are abscessed in a case of that kind, we should not expect that that is necessarily the source of the trouble, but must look still further.

In connection with acute infections, the acute arthritis that we see in rheumatism, a few cases may be of interest. In the first case the patient had gone through the search for foci of infection; his tonsils had been removed, the teeth examined, and a thorough physical examination made. The patient had had repeated attacks of rheumatism which continued for years, and usually occurred in the fall. He came to me in the midst of one of these attacks and on examination I was unable to find any focus of infection that would account for the trouble. This particular attack followed some intestinal disturbance. On three occasions I was able to isolate from the intestinal tract a streptococcus which when injected into animals produced rheumatism. This attack cleared up and I immunized the patient for a long time with the vaccine prepared from the streptococcus from his stool in the hope that some unknown focus in the intestinal tract might clear up.

This patient went south, and while in the South he had some trouble with his teeth. He saw a dentist and the dentist happened to be a man who knew something about the work that Dr. Morehead and Dr. Gilmer are doing in regard to the teeth, and he found an abscessed tooth and pockets of pyorrhea. When he came back I examined the mouth carefully and found no evidence of infection until along the surface of the gums I raised the tissues and found pus pockets. There was not even inflammation on the surfaces, but with a probe I obtained pus from the pockets around the teeth from which I made a culture and produced rheumatism in an animal. The pyorrhea probably had existed for years. This illustrates how difficult it is to locate the focus.

Another case in which the focus of infection was entirely overlooked was that of a young lad who had an acute attack of rheumatism with endocarditis and pericarditis so serious that it was thought he would die. I was asked to see the patient, with some idea, I think, of giving a vaccine. On examination I found that the boy's thumb had been crushed off in an accident ten days before the rheumatism began. I obtained from a necrotic area remaining a culture of a streptococcus like that of rheumatism, and when injected into animals it produced rheumatism readily.

It will be seen that the question of the focus of infection is a matter not only for the stomatologist or the dentist, but for the general practitioner, the surgeon; every branch of medicine needs to be taken into consideration to run the matter down and find the focus from which the organism gains entrance to the body.

PERIDENTAL INFECTION AS A CAUSATIVE FACTOR IN NERVOUS DISEASES *

C. BURNS CRAIG, M.D.
Chief of Clinic, First Division, Neurological Institute
NEW YORK

The presence of pus in a body cavity has long been considered a finding of the utmost importance, of even grave significance, to which an almost innumerable number of symptoms may be attributed. Until recently, however, the existence of pus around the teeth has been lightly regarded and often rejected as a possible cause of serious systematic disorder. The delay in appreciation of the importance of the presence of infection about the teeth is, doubtless, largely due to the familiarity of the physician with the condition in patients whose symptoms seem too remote from the mouth to have any connection with it. Then, too, it cannot be denied that there are persons suffering from pyorrhea alveolaris in whom it has remained a purely local process.

The results of peridental infection would certainly be more disastrous were it not for two fortunate factors of safety, the one, anatomic, the other physiologic. The former is the fact that the pus usually has free drainage into the mouth. The latter factor is the establishment by the body tissues of various degrees of immunity against a continuous bacterial intoxication, for example, from *Bacillus coli communis*. Just as the colon bacillus sometimes overpowers the individual's resistance and produces a general intoxication, a localized collection of pus or septicemia, so may the bacterial flora of the mouth subdue the body resistance and originate an abscess, produce a general intoxication, or entering the blood-stream, may establish a new center of growth in another region of the body.

---

* Read before the Section on Stomatology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

We may well ask is the alveolar pus pocket the depot of origin of brain abscess in those cases the origin of which has been unexplained, in which there has been no abrasion of the skin and no aural or mastoid infection? A purulent process in the posterior urethra, in the vagina or in the tonsil is considered ample source for any arthritis, neuritis or endocarditis which may subsequently develop. Are we not then justified in considering a septic condition around the teeth a source of various disturbed states of health, no other cause existing? Especially is this probable when the correction of the local oral condition is followed by alleviation of the general symptoms. The proof of the responsibility of oral sepsis for certain diseases of the nervous system rests on no other evidence than that just expressed — when the dental condition is corrected the manifestation of disturbance in the nervous system disappears.

Peridental infection is by no means limited to the clinic patient, it is often found in those who have taken the utmost care of their teeth. In these cases the dental work has been faulty and the real status is only revealed by a roentgenogram of the jaw. Crowns and bridge-work are peculiarly liable to have incarcerated pockets of pus.

There seems to be no portion of the nervous system for which the subtle toxin of peridental infection has a predilection. Probably the most common symptom is paresthesia in the fingers and toes—a "pins and needles" sensation—a symptom common to other chronic intoxications. For a considerable period it has been observed that a bad condition of the teeth may be responsible for adjacent disorders, such as otalgia and tic douloureux, but the observation that stubborn neuritis of the sciatic or other nerve trunk or of the brachial plexus sometimes disappears after cleaning out the alveolar disease is of comparatively recent date. The continual swallowing and absorption of pus is undoubtedly the cause of disorders of digestion, headache and finally an anemic condition almost cachectic. This depleted, exhausted state may often be associated with a melancholic state. It seems a far cry from mouth infection to mental disease, but when one witnesses profound depression clear up following the drainage of several alveolar pus-pockets, one is persuaded that the chronic intoxication, the result of absorption from the pent-up infectious process, was an etiologic factor.

Cases of pachymeningitis within the cranium have been attributed by reliable men to peridental infection. Doubtless, also, the peridental membrane has been the portal of entry for infection, causing various forms of arthritis the etiology of which has been obscure. From a variety of disorders the result of peridental infection I have selected four of diverse character whose improvement, following a cleaning up of the dental condition, was rather striking.

Case 1.—Cardiac arhythmia associated with angina: The patient, a surveyor, aged 46, married, temperate in the use of stimulants and tobacco, began to be annoyed in August, 1912, with thumping of his heart at night. These attacks would awaken him out of a sound sleep, would last a few minutes and disappear. At first they occurred about every fortnight, but by December, 1912, the attacks of cardiac thumping were not only occurring every twenty-four hours, but were occurring in the daytime as well as at night.

In addition to the disagreeable pounding of the heart, pain had appeared. The pain at first crossed to the right side of the chest, but later into the left axilla and up the back of the head. This was accompanied by a feeling of anxiety and dread and compulsory immobility. In one attack consciousness almost failed. The only other illnesses the patient had ever had were lead poisoning in 1898 and "typhoid-pneumonia" in 1899. From these he had recovered completely and had enjoyed excellent health until this present illness. Syphilis was denied and the Wassermann reaction was negative. Neither clinically nor by Roentgen ray could anything pathologic be demonstrated in the mediastinum. The heart was of normal size and location. Accompanying the systolic sound was a subdued blowing murmur, and the pulmonic second sound was slightly accentuated. When not in an attack his pulse was regular and rhythmic, 70 per minute, and the systolic blood-pressure was 125 mm. Hg. He exhibited a coarse static manual tremor said to be familial. Examination of the blood, urine and gastric contents revealed nothing abnormal. A slight pyorrhea about the teeth was noticed but was thought insufficient to cause such grave symptoms. He was put on general hygienic and tonic measures and discharged. I was not fortunate enough to see him in an attack. Three months later the patient returned having made very little improvement. Roentgenograms of the jaws were then made and disclosed no less than three pockets of pus about the roots of the teeth. These were opened, drained and treated, and since that time, a period of practically six months, he has been entirely free from cardiac palpitation and its associated angina. Quite recently he writes, "I haven't had a shadow of trouble in the region of my heart."

Case 2.—Persistent periarthritis: A man, aged 46, of good health and temperate habits, free from venereal infection, developed two years previously moderate swelling of the tissues around the middle joint of the right finger. It became painful on movement and any trauma made it worse. Use of the joint, for example, playing golf, also aggravated it, but cessation of vigorous use didn't cure it. He had never been a sufferer from sore throat and was not otherwise rheumatic. He took the "cures" at Aix-le-Bains and Carlsbad without noticeable benefit to the joint. In February, 1914, he noticed some tenderness of a premolar tooth. Examination revealed a slight discharge of pus from the adjacent gum. The tooth was drawn and found to be abscessed at the root. Within a fortnight the periarthritis began to disappear and two months later there was no trace of it.

Case 3.—The commonest symptoms following absorption from peridental infection: A woman, aged 54, complained of "pins and needles" sensation in her hands and feet, pain and tenderness in the muscles of the back and calves, and considerable mental irritability. On examination she was found to be fairly well preserved for her years. Her heart was slightly enlarged in both diameters; pulse 84; blood-pressure 120; auscultation negative. In all the muscles of the back, particularly those above the spine of the scapula, were points tender on pressure; also various points in the intercostal spaces were tender on pressure, especially the left border of cardiac dulness. Squeezing the muscles of the arms and calves caused considerable pain. There was no definite nerve-trunk tenderness. Besides this the physical examination showed nothing of significance except a profound pyorrhea alveolaris.

After a week of eliminative and tonic measures, during which no improvement was evident, she was advised to have the dental condition remedied. A dentist extracted several carious roots and cleaned up the pyorrhea around the better preserved teeth. Within two weeks her gums looked comparatively healthy. Coincident with the improvement in her oral condition the tender points in her muscles and the paresthesia in the hands and feet diminished. Eliminative methods were continued for another three weeks, at the end of which time her muscles were in a comparatively normal state.

Case 4.—Presenting a picture of an agitated depression in which the presence of alveolar pyorrhea of long standing was evidently an important exciting factor, but not, perhaps, the primary cause:

The patient, a woman, aged 59, well preserved and of more than average mentality. She sprang from a long-lived non-nervous stock; she had passed through the climacterian twelve years before without unusual disturbance. During the past three years she had sustained a series of shocks with great fortitude and for the time being without telling effect on her nervous system. Three years previous she lost her father, a year later her mother died. During the week of her mother's death she had had a nasal operation performed. Soon after this, financial losses occurred which were the cause of considerable worry. The patient continued in reasonably good health for over a year, that is, until six months previous to entering the hospital. At that time she went to a fashionable sanatorium, more as a pleasure resort than for treatment. While there she began to have attacks of dizziness. A physician told her she was suffering from mild heart-disease and prescribed Nauheim baths. After she had taken eleven baths the present "nervous breakdown" began.

When first seen the patient was greatly depressed and nearly always in a state of agitation, pacing the floor restlessly and recalling the loss of her mother as the greatest disaster in her life and weeping bitterly during every conversation. She said she was convinced she would not recover. At other times she spoke in a mournful tone without being able to give the exact cause of her depression.

Physical examination was entirely negative, except for a pulse of 100 and the condition of her teeth. Heart was of normal size and without pathologic sound. The stool when examined proved normal, except for slight evidence of catarrhal colitis. Blood examination showed hemoglobin 78 per cent.; red blood-cells, 4,869,000; white blood-cells, 6,500; differential showed mild increase in the lymphocytes; the urine was normal. A test breakfast showed diminution in the hydrochloric acid content. A serum Wassermann was negative, and the spinal fluid was normal in every respect.

After a week of tonic measures without noticeable improvement it was decided to subject the patient to the ordeal of having her dental condition improved. A roentgenogram of the jaw showed two abscessed roots under crowned teeth and a collection of pus beneath a faulty bridge.

The bridge-work was removed and abscesses drained. During the following week the cloud began to lift, and she began to have moments of better humor and saw some possibility of looking at the brighter side of things. The patient was then sent to the country for two weeks from which she returned in a comparatively happy state of mind. She arranged to take some hydrotherapy treatment at the hospital, but a few days later decided to go visiting instead.

The message of this paper is that the obvious is too often disregarded in searching for some profound cause. The discovery of a purulent process similar to that frequently seen in the mouth in other regions of the body would be sufficient ground for the hasty summons of the surgeon. A full appreciation of the possible dangers from infection around the teeth should lead us into council with the dentist. This is in no sense a criticism of the dental profession, but rather a plea for the closer cooperation of the medical man and the dentist. After an expert dentist has properly cleaned up alveolar pyorrhea or abscess, we find vaccines, as a usual thing, unnecessary.

37 West Fifty-Fourth Street.

ABSTRACT OF DISCUSSION OF SYMPOSIUM ON MOUTH INFECTIONS

Dr. Arthur D. Black, Chicago: One phase of this subject, of interest to both dentist and physician, which has not received the consideration that it should, concerns the pathologic changes that take place in the tissues which are involved in the establishment of these foci in the mouth. We have in the mouth two groups of chronic foci, the chronic alveolar abscess and the so-called pyorrhea pocket, both of which involve a single tissue—the peridental membrane—which is the important factor in establishing the chronicity of both groups of cases. As a result of the involvement of the peridental membrane, either at the apex of the root or beginning at the gingival margin, there is a suppurative destruction of the attachment of the tissue, to the cementum covering the root of the tooth. As a part of this process the cementoblasts, which overlie the surface of the cementum within the peridental membrane, are also destroyed. These are the only cells which could cause reattachment of that tissue. Soon after detachment, the fibers of the peridental membrane, which passed from the cementum of the detached area to the bone, disappear, and a little later the bone to which they were attached is absorbed. Thus all of the specialized elements necessary to the connection of root with bone are lost, and we cannot have reattachment of this tissue to the cementum of the root. This is shown very clearly by the roentgenogram in both groups of cases. Careful examination of these will show a line down the side of and close against the root, which is practically always in advance of destruction of the tissue elsewhere, showing clearly that this disease has begun at the junction of the peridental membrane and the cementum. There is a progressive involvement of peridental membrane and bone, making the whole area about a given tooth funnel-shaped. Within the past few years I have cut away the tissue forming these pockets from the roots of teeth for microscopic examination. In one case I removed the tooth, peridental membrane and a section of the alveolar process and overlying gum tissue all in one piece, and had sections made for study. These sections show that the above mentioned changes take place and that detachments are permanent. Therefore pockets remain about such teeth and the overlying tissue is subject to frequent reinfection. We should not, therefore, expect vaccines to have any more than temporary effect on the local focus, because we have a condition here in which the physiologic possibility of repair is gone. The dental treatment indicated is the elimination of the focus in the case of the alveolar abscess by resecting the denuded root end, or the extraction of the tooth. If it is a pocket alongside the root, exposed to the fluids of the mouth, the tooth must be extracted, or palliative treatment employed which will be effective against reinfections.

Dr. M. I. Schamberg, New York: Dr. Billings gave a clear and concise description of the mode by which infections of the mouth reach these parts, and I was disappointed that he did not, even cursorily, touch on the possibility of a septic endocarditis, and likewise of producing secondary infections about the body other than those that apply to arthritis deformans. I, with many others, have been observing these conditions for a number of years. Our findings have been largely clinical up to within possibly a year or two, since which time, through the cooperation of the laboratory and the medical diagnostician and interns, we have been able conclusively to prove that the mouth is a prolific source of primary infection, bringing about serious sequellae. It is equally important that we remember that the absence in the roentgenogram of the dark area is not essential to the conviction of a particular tooth as the cause of these secondary troubles. Only recently in a case in which we were anxious to find the bacterium producing the effect on the patient's general health, a tooth was removed which showed an incomplete root-canal filling with no apical disturbance whatever. On crushing off, under aseptic conditions, the tip of this tooth, from the putrescent material in the apical end of the canal we were able to grow a pure culture of *Streptococcus viridans*. Likewise, in a case of rheumatoid arthritis of fourteen years standing, the patient, who was unable to walk, was brought in with a history of a thorough survey of the mouth for any possible etiologic factor in that region. I finally found among the few remaining teeth a tooth that had been comfortable through all these years, but the roentgenogram showed a slight area about the end. We removed the tooth and from it produced a pure culture of *Streptococcus viridans*. In this case the history of the work done on the teeth recorded that it had been treated some sixteen years previously, which was two years prior to the

Another young man had gone six weeks with serious symptoms of general infection represented by chills and fevers, serious suggestion of malarial fever, but a diagnosis was made of septic endocarditis. It was impossible to find any indication or ordinary physical manifestation. We looked thoroughly for the focus of infection but found nothing except that in the throat the tonsils seemed to be unhealthy. I suggested that a throat specialist be consulted. The specialist discovered an abscess. The cavity was irrigated and the temperature went to normal in twenty-four hours; the patient had no further chills or fever and finally recovered. It has been my privilege occasionally to see lesions about the mouth which did not respond to treatment, in which cases the Wassermann test proved positive and the patient, put on salvarsan, recovered.

These cases illustrate the opinion, I think, that the mouth furnishes a large proportion of infection which we overlook. We in general practice find a large proportion of people who never saw a tooth brush; who do not know anything about the care of the mouth. If these cases were considered by the physician with reference to inspection of the mouth more generally, more patients would be referred to the dentist and have carried out mouth sanitation in the proper way.

Dr. Henry W. Frauenthal, New York: We have made it a routine practice by means of a dentist connected with the institution to have all the teeth examined, and it has been remarkable to see how many chronic joint conditions are benefited by cleaning the teeth. I think one of the most common sources of infection has been in poorly built bridges and caps, work done indifferently, in cases in which infection existed. On removing the caps we find infection existing. A number of these cases have been shown in the New York Dental Clinic. A patient on my service had been treated for rheumatism in several institutions previous to admission to the hospital without any benefit whatever. Her pain was so acute that she attempted to commit suicide twice, having been informed that her condition was chronic, and would never improve, but on the contrary, would gradually grow worse. Owing to the condition of her gums, I made a diagnosis of joint condition due to septic pyorrhea alveolaris and with no other treatment but the correction of the mouth infection, as done by Dr. Harry A. Goldberg, an arthritis involving both knees, left ankle, right wrist and elbow, cleared up in ten days, and at the end of three weeks the patient was discharged cured. Her temperature varied from 98 to 102 F., with a corresponding pulse. This condition extending over a period of nine months, responded to treatment in ten days.

Dr. T. W. Corwin, Newark, N. J.: In regard to the search for the foci of infection, two points may be of interest. For instance, the appearance of the tonsils may be quite normal, but if the routine practice is adopted of making pressure on the tonsils with some instrument, frequently one will find an exudation from the crypts of matter which may be worth while investigating. Another simple procedure that I believe will prove valuable in many cases, and especially those in which there is a manifestation of anemia, is, whether it is necessary to make an observation of the temperature or not, to put the clinical thermometer under the tongue; before reading the temperature, if you will pass the end of the thermometer under your nose, frequently you will discover a fetid smell. Perhaps these two little points may be of assistance when searching for the focus of infection.

Dr. W. H. Mercur, Pittsburgh: I read a paper not long ago by Dr. Morris Manges of New York on the "Mouth as a Means of Diagnosis." I have met but few men who have read it; it is certainly most appropriate to the present discussion. In this article he shows how easy it is to examine the mouth and how hard it is to examine the stomach and other organs that we give so much attention to. In this article I think he speaks of eighteen different diseases which can be absolutely diagnosed from inspection of the mouth alone.

Dr. J. A. Pettit, Portland, Ore.: I have put on record a number of cases which have come through our service, illustrative of the salient points brought out here. Many of us have had experiences in this connection, which are similar in the gross, but vary in minor details. We are undoubtedly entering on a new era of therapeutics, medically as well as surgically. This subject is undoubtedly in the early stage of development; what the next few years will bring forth is hard to tell. Instead of bending our efforts to the relief of the ravages of infection, we are searching for the sources of infection and reaching out with the use of vaccines and other remedies to overcome them. This is the broad field of therapeutics of the coming day. Preventive medicine is gradually extending out and overshadowing the former field of materia medica and drug therapeutics. Heretofore, remedies have been applied for the relief of conditions which we are now able to prevent. In the face of all the admirable and life-saving work done by medical research and study, it is disgusting to be compelled to listen in dignified silence to the malevolence of ignorance displayed by various cults, and at the same time observe them taking advantage of the very life-saving procedures which the medical profession has discovered and devised.

Dr. Frank Billings, Chicago: In my address I did not go into the details of every variety of disease that seems to be related to focal infection, but rather tried to give the principles of it. I think we should not use the word "cause" too much in relation to the focus of infection of a systemic disease. We should not, even with the focus before us, say that that focus is the absolute cause. I think we will have to use the expression that it is the predominating etiologic factor because there are so many other factors to be taken into account. None of us, it does not matter what our position in the profession may be, is capable of passing judgment on all things, and for that reason we have at the Rush Medical College clinic endeavored to encourage what we call team-work. I, myself, never pass on a special infection except when it is related to something that I think I am a better judge of than the other men. For instance, Dr. Moorehead is asked to pass judgment on the mouth, so far as the jaws are concerned, and I make him responsible. The best men in their lines, men who are teachers in the college, I ask to give judgment about an infection of the sinus or tonsil. Sometimes we call surgeons in with reference to some infection in the abdomen or elsewhere that I think may add to my own knowledge of the condition before we proceed to do anything. I do not pretend to-day to carry out the technic in bacteriology. We have such men as Drs. Rosenow, D. J. Davis, H. K. Nicoll, Gaarde and other bacteriologists, working at the problems. We must all get together. The oral surgeon has no right to diagnose a systemic condition of the patient and say outright that the mouth is related to it; he should have the family physician cooperating with him before he reaches that point. Nor should the family physician nor the one having general management of the patient order teeth out without the definite advice of the oral surgeon who is capable of giving it. I believe there is much in that principle that there is a focus of infection that is the predominating factor in many systemic diseases. This is perhaps expressed more commonly in arthritis of the chronic type than in any other disease that we can mention, but it is in many. Besides arthritis, we have traced this same hematogenous infection with its embolic occlusion of the end artery as the cause of cholecystitis. Hyperplasia in the thyroid gland, which occurs commonly in rheumatism, is associated with infection of the tonsils. The hyperplasia disappears with all of the clinical phenomena with the cessation of the tonsillitis. Also in hemorrhagic nephritis, the streptococcus obtained from that producing tonsillitis, causes hemorrhagic nephritis in the animal, etc. So that the application of the principle is much wider than the average practitioner thinks.

Dr. Thomas Gilmer, Chicago: To find the cause of a condition and locate its origin is all-important, but we must go further back than this. Infections in the mouth are due, in the great majority of cases, to improper hygiene. We all recognize the uncleanly condition found in nine-tenths of the mouths which come under our professional care, although the patient may be otherwise scrupulously clean. I venture to say that if we should examine the mouths of the physicians in attendance in the various sections here to-day, few would be found clean, or even approximating a hygienic condition. It is well to cure our patients when they become diseased, but it is far better to prevent disease by teaching the people the importance of the care of their mouths, that they may not suffer from disease primarily brought about by lack of care of the teeth. Dr. Blair asked if I considered it important to curet and disinfect bone cavities after the removal of a tooth with a septic apex. As a rule I should answer in the negative. The curettement depends, of course, on the stage of the infection and the area involved. Chronic abscesses may be profitably curetted in some cases, but in the acute cases it should never be done. In acute cases I am doubtful about the use of antiseptics. I think it would be just as well to use simply a normal salt solution. Antiseptics, if strong enough to destroy bacteria, would prove detrimental to the tissues; besides we cannot penetrate the tissues with an antiseptic so far as the bacteria have gone. Is it not true that by curettement we cause a greater traumatism which renders the tissues more liable to greater infection?

SOME IMPORTANT PHASES OF RAILWAY SANITATION *

A. E. CAMPBELL, M.D.
Health Officer Illinois Central Railroad
CHICAGO

The steamship and the railway are making the world one country. Produce is now carried from Australia to England, a distance of 11,000 miles, at less cost than was required a hundred years ago to carry goods from one end of the British Isles to the other. The construction of our transcontinental railway systems soon after our Civil War, the projection of great railway systems in Russia and continental Europe in 1873, the opening of the Suez canal in 1869 and the Panama canal in 1914, made all civilized nations near neighbors.

There were carried on the Great lakes last year 7,000,000 people. The Chicago City Railway handles 3,000,000 persons each day. The suburban lines of Chicago handled 44,347,680 persons in the year 1913. The Illinois Central Railroad handles on an average 40,757 persons on her suburban lines each day, or 14,876,300 persons each year. This requires a vast amount of care and responsibility. The railroads leaving Chicago each employ from 45,000 to 74,000 people and the care and working conditions of this army of men should be supervised by an intelligent man. He should have supervision over the ventilation of trains, the condition of the diners, the cleanliness of the depots and toilets, as well as the ventilation of waiting-rooms, the condition of all eating-houses along the line, the condition of shops and yard-offices, repair tracks, construction crews and a hundred other duties which are sure to come before him. I can assure all railroads that such a man will have all he can attend to and will be well worth what he costs many times over.

THE TRAIN

The ventilation of trains or at least of the day coach is not a difficult problem if one or two points are kept in mind. A train rushing against a strong wind causes the air to pass through a train horizontally—hence, if there are openings in the end of the coach the air will pass through, as I have repeatedly proved. All end doors of all coaches should therefore have adjustable sash and the sash in the rear door should always be open. Every coach should have a thermometer and the temperature should be kept at a certain figure. The steel coach is coming more and more into use on account of its safety, and in the South this coach becomes very hot. I have found that the temperature in the center of this coach is from 2 to 4 degrees higher than in the ends and as the electric fans are in the ends they are cooling the part of the coach that is cooler anyway. There should be two oscillating fans in the center of the coach, but if four fans consume too much electricity, three English paddle fans should be installed 15 feet apart. This will distribute the air more evenly.

Spitting on trains is so reprehensible that I believe a slip should be issued by all railroads and used in the state through which they run as follows: "In view of the authority vested in the State Board of Health you are liable to a fine of $25 for spitting, sneezing or coughing on trains without taking the precautions mentioned on this slip." On the back of the slip instructions should be given where to spit and how to cough and sneeze with the handkerchief before the face. Railroads do not like to displease their patrons and state boards should assist and issue these in the name and by the authority of the state board and thus help to stop this disgusting practice on trains.

All coaches should have separate apartments for water and ice. I see ice handled so carelessly—slid along a platform over tobacco spit and other unmentionable filth, laborers taking up the ice with their bare hands and dumping it into the drinking-water—that I have very firm convictions on this point. I do not believe it is wise to have ice in the water in our dining service, mainly because of the methods of handling the ice. Then, again, this ice is handled by a cheap class of laborers who are not overly clean and tidy and I hope all railroads will abandon the placing of ice in the drinking water on trains or on diners.

There should be a folding washbowl near the pantry in all diners, but I strongly object to a toilet in a diner, as no person would care to have odor from a toilet come to his nostrils while eating. All waiters should be instructed to wash their hands before serving food and this would be a good rule to follow in all railroad lunch rooms. It is not very appetizing to see a waitress fix her hair and pick her nose and then without washing her hands hand a piece of pie or come with her finger in the glass of milk. It is because these very matters have come under my observation that I speak of them.

The carriage of tuberculous people on trains has caused much comment and in some states attempts at legislation. We cannot deny that there is a degree of danger, but no more than from many other diseases. There is no denying the fact that diseases are transmitted from person to person and usually can be traced to excretions thrown off from the infected mouth and nose. Indeed we are all more or less exposed to this wide-spread infection at some time or other in our lives. From the best authority we can find we fail to gather information that a person traveling on a train or steamboat reasonably well ventilated would contract consumption, even though there is consumption among his fellow passengers. There is absolutely no evidence proving such incidence of infection. Yet there may be individual cases which may point to such a possibility; but they do not prove it. Other evidence, however, leads us to suspect that the journey on the passenger coach has little or nothing to do with it. The chief physician of a great sanitarium for tuberculosis told me that it would be impossible for the common carrier to segregate those cases, as there were thousands seemingly well or healthy individuals who excrete tubercle bacilli in abundance. Indeed, I believe it would be well for common carriers to have literature on tuberculosis, or it might be well for state boards to have literature telling how the tuberculous patient should behave to protect himself and the public. For instance, the following rules might be circulated.

---

* Read before the Section on Preventive Medicine and Public Health at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

INSTRUCTIONS TO TUBERCULOUS PATIENTS

The tuberculous patient must consider his own welfare as well as the welfare of those about him.

1. He should be in the fresh air as much as possible night and day.
2. He should be cheerful, look on the bright side of life.
3. He should eat only nourishing food—meat, vegetables, bread, buttermilk, cream, eggs.
4. He should avoid style, dress to suit the changes in the weather, always carry an overcoat and two or three handkerchiefs.
5. He should keep his nose, mouth and hands clean.
6. He should take at least nine hours of sleep at night, and if possible a nap in the afternoon.

SOME THINGS THE TUBERCULOUS PATIENT SHOULD NOT DO

1. He should not mingle in large crowds of people or be where there is dust or smoke.
2. He should not take tobacco or alcohol in any form.
3. He should not cough needlessly, but only when he feels he must expectorate.
4. He should not work when feeling ill.
5. He should never swallow his sputum, as it may cause tuberculosis of the bowels.

SOME THINGS THE TUBERCULOUS PATIENT SHOULD NOT DO, FOR THE WELFARE OF OTHERS

1. He should not spit anywhere except in vessels for that purpose or in paper napkins, which should always be burned.
2. He should not cough or sneeze without covering mouth and nose with handkerchief.
3. He should not kiss any person.
4. He should not eat or drink from dishes that may be used by others.
5. He should not sleep in the same bed with another person.
6. If riding on a train he should always take a state room or a berth in the rear end of the car and have cuspidors and paper near him and expectorate only in them.

I believe something like this should be carried by all common carriers and I feel confident state boards could aid common carriers very materially by having something like this in such public places as the waiting-rooms of depots, etc. It would be well for state boards to distribute some literature to this class so that if they travel they can be informed of the precautions they are expected to take.

Tipping on trains and on Pullman sleepers has gone so far that it has become a menace to the traveling public. There are many hotels and many more restaurants which forbid tipping. One of the leading hotels in St. Louis prohibits tipping. The McKinley electric lines through Illinois prohibit tipping on all their trains and it is time for all railroads and the Pullman people to get away from it. It is undignified and un-American and the quicker we stamp it out of this country the more we will dignify ourselves in the eyes of foreign nations.

I quote from the Washington *Post* to the effect that a young man paid three thousand dollars a year to his employer and hired several clerks and became rich in a short time. This shows how insidious a vice this is becoming. Not a man who is a member of any organization but condemns this vicious practice in the strongest terms, and railroads and the Pullman companies as well as all other corporations should bid adieu to this undignified practice.

The "butcher" or fruit vender on trains, with dirty hands and dirty linen, is a nuisance to many passengers and I believe often disseminates disease. One of our surgeons told me of a fruit vender he was treating for a specific disease, who came from the toilet room without washing his hands, handled and sold fruit to a woman with a young child. In the course of a few days the child was brought to the surgeon with a very sore eye which proved to be a gonorrheal ophthalmia. Not only should fruit venders be urged to wash their hands and keep clean but they should be examined regularly as well as all dining-car employees.

THE TRACK

There is much agitation over track pollution by interstate carriers and although I have watched for the number using the toilet I was unable to determine how much fecal matter was discharged. I therefore selected the part of our road having the heaviest travel through the central part of Illinois. Starting at Centralia at 9 a. m., with buckets under all hoppers and traveling 275 miles with 564 passengers there were three bowel movements and much urine. Returning at 10:30 a. m., the same distance, with 645 passengers there were but two bowel movements and much urine. Next, the train from Chicago to St. Louis was taken. This train leaving at 10:05 a. m. with 193 passengers, arrived at St. Louis at 6:45 p. m. There were no bowel movements but much urine. Returning, a distance of 300 miles with 394 passengers, arriving in Chicago in eight hours, there were no bowel movements and very little urine. There is no doubt but there is much urine thrown off, but the constant jarring of the coaches inhibits the peristaltic action of the bowels in the vast majority of traveling people. The secretary of one of the boards of the Northwest told me that he has traveled from Winnipeg to New York and return without a bowel movement. Urine as it leaves the body is said to be aseptic and providing typhoid germs are thus thrown off, sand or gravel is not the soil in which they can long survive, and there must be a relation between the seed and the soil. It is not wholly the one or the other with which we have to deal as practical men. It is the combination and the interaction between the two. I have also made a careful inspection of our main track over which our through trains pass between the hours of 9 and 12—the hours when bowel movements are most likely to occur. In company sometimes with state or city health officers and railway officials we failed to find any evidence of human excrement and the railroad official explained that the constant fanning of the long freight and passenger trains dried out all human excrement. We did see an unusual amount of cattle manure, however, and as it is said that cow manure contains the colon bacilli, this matter should be seriously considered, for cattle are just as likely to drop their excrement directly into the water. It is no more dangerous for cattle to drop this on the track than beyond the fence by the right of way, but from an esthetic point of view it would be well for railroads to prevent as far as possible the dropping of this occasional movement on the sidewalks of cities and villages and I believe a false trap could be attached to the bottom of all hoppers or there could be a lock put on the flush bar or handle so that this could be flushed at points where there was no danger of sidewalk pollution. I am very sure this can be done. At some points where our sleepers stand over night there should be a bucket under all hoppers and the toilets left unlocked for the convenience of the passengers. Cattle pens along the line should be kept clean and whitewashed.

CONSTRUCTION AND SURVEYING CREWS

I have on two former occasions called attention to this class of work and it seems that very few railroads and scarcely any state boards in this country have taken cognizance of this important part of sanitary work. When I called attention to this phase of the work—three hundred men throwing their excretions everywhere along the track while at work—I was curtly asked if three hundred was any worse than sixty passengers dropping their excretions on the right of way, when in reality not four persons drop their excretions in a journey of 300 miles. I have seen so much of this that I again call attention to it and have laid down some rules that should be followed. I have also designated the equipment that all camp cars should carry, as I often find them with no lime, no kerosene, nothing to destroy bedbugs or body-lice. Often small-pox breaks out among this class of laborers. Often gonorrhea is prevalent and it is important that separate towels should be provided for the men. I strongly recommend that these instructions be given to those in charge of camp cars:

INSTRUCTIONS TO BE GIVEN TO THOSE IN CHARGE OF CAMP CARS

1. See that all cars are properly screened and ventilated.
2. See that all cars have the following equipment: a portable toilet; a barrel of lime; one-half barrel of powdered sabadilla; 5 gallons of kerosene; one covered garbage can; 50 pounds of sal soda; one 14-inch rattan scrub broom; soft soap; wash pans; towels and a fly-swatter for each car, and 1,000 3-grain quinin capsules. Vaccinate all men.
3. Assign a man three hours each day to scrub kitchen and dining-room, and all sleeping-rooms every other day, to air all bedding, to ventilate all sleeping-rooms, scrub and lime all closets, and to see that fresh water is provided for all the workingmen. If in a low marshy region 3 grains of quinin shou.d be given twice daily.
4. See that but eight men are assigned to a car and that all cars have sanitary beds.
5. See that all garbage is destroyed or gotten rid of each day.
6. When building a privy dig a vault 5 feet deep and 2 feet wide and as long as needed, then put 6 inches of unslacked lime in the bottom and cover deposits daily with lime.

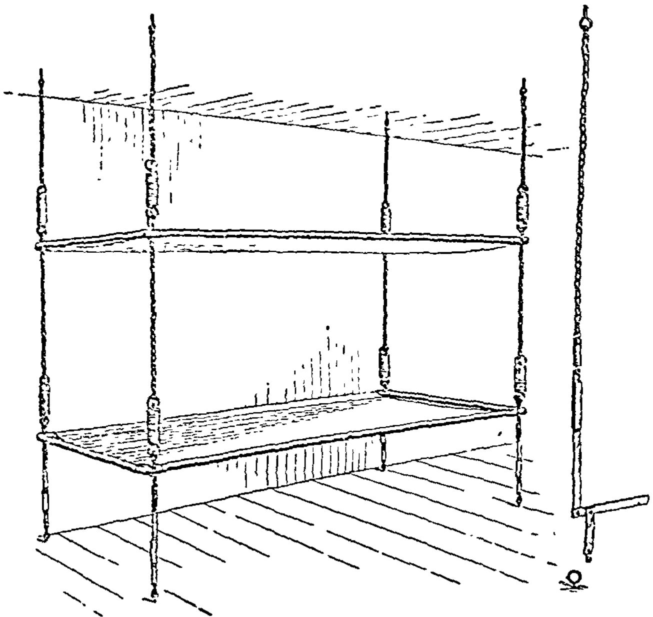

Fig. 2.—Sanitary canvas beds. Our company installed a large number of these beds in all our camp cars. They can be taken down and sunned and aired; combine simplicity with cleanliness; the canvas can be easily removed and washed.

The privy vault at small railway stations is a necessity and if it has fallen into disrepute it is because of neglect. I am confident that it is far superior to Stiles' bucket as it is much easier to cover the excretions in a vault already made than to make a vault and then cover it afer carrying this offensive mass for some distance. Dr. Smith in his *Air and Rain*, says:

> If soil affects the atmosphere how does it happen that it is such an excellent disinfectant? Substances are purified in the air to the same extent, and in the same time as in the soil. The great amount of surface presented by the porous soil is *mainly the cause of the rapid reaction, but the acid humates* and probably other substances act chemically. There are modes of oxidizing in the air beyond the power of ordinary oxygen; one of these is by means of nitrogen oxids and another by ozone. But even these require great time and space. If we throw sulphureted hydrogen water or its compound with ammonia on a few inches of soil it passes through, oxidized in a few minutes. We can obtain such *action in the air only in great volume* although in the end the work done may be better for its purpose. It is, however, possible to overload even the porous soils which oxidize the most rapidly; that is, it is possible in a given case to have more organic matter than admits of oxidation in a certain time and putrefaction is the first result.

Now if soil is used freely, say three times as much soil as excreta, this putrefaction will soon disappear and, indeed, may be prevented as I have repeatedly demonstrated. The plan we have adopted and which I can recommend is to dig a vault 5 feet deep, then put 6 inches of pure unslacked chlorid of lime in the bottom. Save *all the earth* removed from the vault and add this each day or twice a week, and when the vault is full use this as a fertilizer. There will *not* be a particle of odor and except a few streaks through the soil one could not tell it from the ordinary soil. I have had section men dig down over a privy vault three months or more after it was abandoned and we could not tell it from ordinary soil. This, however, was exposed to heavy rains. If this soil is used as fertilizer it should not be used in gardens for one year at least.

The care of the excreta of fifty men at our shops and small terminals where there is no sewerage is another matter, however, and I am using an incinerator, and in some places where there is a pump engine boiler the excreta can easily be burnt in this. If not, then a castaway engine grate can be used by having it raised 12 inches from the ground, building a hot fire under it, throwing kindling wet with kerosene on this grate and adding the excreta and some tar to keep down odor. It is surprising how effectually tar will keep down odor. I have also used creosoted pile heads, which keep down odor very well. This is a method which all railroads can easily use and should use as a safe measure. There are always a lot of odds and ends to be burned at all shops and these could be used at this time.

We have a great amount of trouble at our stations by having our toilets abused by people who are not patrons of the railroad. If state boards and the public health service could insist that all municipalities have public toilets as they should, railroads would not have so much trouble with theirs. We often get notice from a health officer that we must install a privy at a certain place when it is used almost exclusively by citizens of the town who never patronize the road. Why should not these public officials get after municipalities which have such an army of worthless people to provide toilets for them? Other countries have them and state boards should insist that all large municipalities have public toilets.

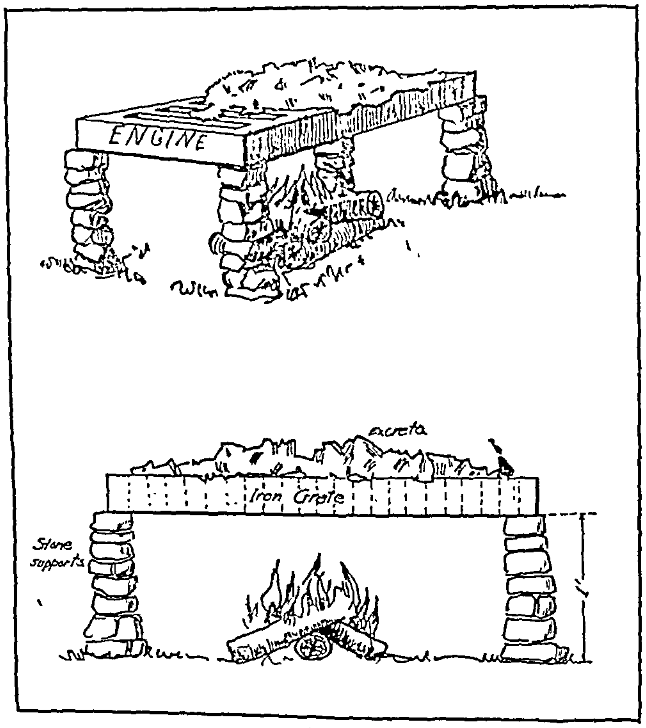

Fig. 3.—A method of disposing of excreta by incineration.

THE SHOPS

When the railroad shops are built in a swamp, as they usually are, proper drainage should be provided and drinking-water looked for at once. This drinking-water should not be taken from the tank, as I have frequently found, until the source of such water is ascertained. There should be ventilators over the forges in the blacksmith shop and the master mechanic's office should be so located that smoke and gas from the engines would not come near it. Indeed, all general offices should be so located that gas and smoke would not be offensive. I have firm convictions on this point. It would seem more accurate and perhaps wiser to deal with the human being as if he were a machine, with his efficiency as measured by his output, and endeavor to find what the conditions are which lower his efficiency. Sir Thomas Oliver in his masterly address on "Dust and Fumes, Foes of Industrial Life," pointed out the human and economic aspect of the work in which we are engaged. Indeed, it is estimated that nearly 70,000 wage-earners perish every year from industrial tuberculosis and that by factory inspection and effective methods for the prevention and removal of dust and gas fully one-half of these lives could be saved. This is not speculative, and abundant evidence can be produced that gas and smoke and fumes of gas are detrimental to the public health as well as lowering to the efficiency—either impairing it temporarily or tending to impair it permanently. I can also testify to the fact that this gas from engines prevents the proper ventilation of offices, and since such statements are true I urge all railroads to have their offices in the country. Our company has 50 acres 15 miles from Central Station and why would it not be wise to build offices at this place with outside porches, swimming pool, abundant shower-baths and a large park for general games at the noon hour? Not a man reading these lines but will say that such a step would increase the efficiency of the working force and be a credit to the management.

Noise would also be avoided; indeed, the blowing of whistles and constant ringing of bells when the train is standing still is a nuisance and is prohibited by many municipalities. M. Emile Gautier declares Paris is becomming uninhabitable because of noise. Every pulsation and noise, he explains, causes nervous shock, comparable to a blow with a hammer, and is felt throughout the entire cerebral mass. These shocks are liable to cause or to create serious trouble. Experts who have studied the noises of Paris and their effects on the nerves and brain matter are convinced that the modern malady of neurasthenia is directly attributable to the riot of sounds by which we are daily assailed. No other explanation is needed for the growing number of nervous disorders. The pledge given Mrs. Rice by a little child in her campaign against unnecessary noise is wise and should be practiced by all trainmen—"I promise not to play near or around a hospital, when I do pass I will keep my mouth shut tight, because there are many invalids there, nor will I make myself a perfect nuisance."

ABSTRACT OF DISCUSSION

Dr. A. M. Harvey, Chicago: Certain corporations have had medical health departments for over a quarter of a century, and the appointment of such an officer is becoming quite universal among the large corporations. About a month ago in an investigation among the larger industries of the United States, I received something like thirty replies to my inquiry which covered several questions: "Do you maintain a health department?" "Do you examine men physically?" "If you do maintain a health department, is it in control of a physician, and what voice does he have in the management?" Of the replies received from corporations that were fairly representative of the industries in our country, and probably employed several hundreds of thousands of men, about 70 per cent. of the answers showed that they examined, physically, all applicants for work before employing them. That simply indicates the interest that corporations as employers of labor are taking in the health problem. The importance of medical supervision of health in industry is also emphasized by recent legislation in several states whereby it is made mandatory in certain trades and occupations, and by sanitary regulations imposed on employers in general. Among the advantages claimed for corporate or private medical health departments are: 1. Safeguarding the health of employees from the dangers of those seeking employment who may be afflicted with dangerous or infectious diseases. 2. The assurance of a fairly good working force from the beginning, by the physical examination of applicants. 3. Affording employees opportunity for early consultation, before an ailment has become established, thereby giving them the best chance for a cure. Employees are prohibited from returning to work before convalescence is well advanced, thus insuring a permanent cure. Employees in hazardous positions by reason of physical infirmities are placed in positions of security. Loss of time on account of sickness is lessened. Sanitary conditions of shops and offices, and favorable working conditions and environments are insured by personal inspection by sanitary experts. Prevention of disease, like the prevention of accidents, insures a more efficient working force. The health department in a corporation increases the efficiency and earning power of the men. Judged by the great amount of money that has been expended in this direction by several large corporations, notably the Crane Company, the International Harvester, and the United States Steel and their subsidiary corporations, the health department pays; and the housing and living conditions have also been improved. A wonderful change can be brought about by a health officer who has the confidence of the corporations; but much yet must be done. The great work at present is to improve the living and housing conditions of the employees.

Dr. J. W. Kerr, Washington, D. C.: Dr. Campbell mentions a number of problems that are of interest to the traveling public. The term "car sanitation" is somewhat indefinite. It must, of necessity, include more than the sanitation of the cars, just as industrial hygiene must include more than sanitation of shops; for instance, the economic and sanitary conditions in the homes of laborers. It is important for us to approach these problems without prejudice. From the point of view of comfort and convenience, generally, the railroads of our country are in advance of the people who travel on them. I had occasion, recently, to compare the sanitation of our cars with those of foreign countries. A standing order in the Treasury Department requires any medical officer of the Public Health Service who travels under official orders, as soon as he returns to his station, to submit a report on the sanitary condition of the trains occupied. This report is immediately forwarded to the Secretary of the Treasury, and is then returned to the Bureau, and any criticism contained in the report is brought to the attention of the railroad company, if it is severe enough to warrant such action. Under this order I made an inspection of a train on the Baltimore and Ohio Railroad, running from Washington to New York. Like inspections were made in Europe of trains operated over state and privately owned railroads. On the American train there were no common towels, and liquid soap was furnished in every car. The toilets were clean, and locked up while crossing waterways. In other respects this train was in good sanitary condition, and the railroad stations at both terminals were also in good condition. Many of the trains occupied on the continent, on the other hand, with the exception of the train from Cherbourg to Paris, were abominable; and some of them were state-owned, state-operated roads. This experience is cited as evidence that the railroad companies of America are trying to meet reasonable requests of the traveling public, and they are approaching these problems from a practical point of view. I think they want to improve conditions. One of the subjects needing careful study is the influence on health of gases in tunnels. Within the year a number of samples of gases have been collected by the Public Health Service from tunnels used by coal-burning engines and electrically operated engines, respectively. The results of the analyses have been tabulated and are now in press. Studies are also being continued, of the extent of the migration of tuberculous persons in interstate traffic. There are about five or six areas to which tuberculous persons from all sections of the country travel for changes of climate. We know nothing, however, of the volume of this travel; and we know very little of its effect on the public health. The regulation of it is difficult; and for that reason probably has not been as fully studied as it ought to be.

Dr. John W. S. McCullough, Toronto, Ont.: Railway sanitation is a serious problem in our country because railway construction is active there. Dr. Campbell referred, however, to other carriers; and that allows me to speak of the pollution of the waters of the Great Lakes separating Canada from the United States. Last year, at the instance of the international joint commission, our board of health, in conjunction with the United States Public Health Service and some state boards of health bordering on these waters, made an extensive examination of the waters of the Great Lakes and connecting rivers. This investigation, which lasted from April to November and is perhaps the largest undertaking of a similar character ever completed by any of the countries of the world, demonstrated that while the lakes themselves are practically pure, the connecting rivers and portions of these lakes are dangerous to those who travel on them. When the enormous commercial and passenger traffic on the Great Lakes is recollected and also that the incidence of typhoid fever in the towns on the Great Lakes is the largest found in any part of these countries the dangers to the traveling public on these lakes is of deep concern. It was demonstrated that St. Mary's River, St. Clair, Detroit, Niagara and St. Lawrence rivers were badly polluted; in fact, there are portions of the Detroit River which are so polluted as to be unfit for use after the most careful purification. None of the water of the St. Clair, St. Mary's, Niagara or Detroit rivers is fit for use without purification. From the mouth of the Niagara River the pollution is carried out into Lake Ontario for a distance of from 10 to 16 miles. Lake Ontario, in the line of boat traffic from Niagara to Toronto, is only 30 miles wide, hence this pollution travels across the international boundary; and in the line of this large traffic it is impossible to secure a pure supply of water for these boats without taking it from some source other than from the lake itself. I hope all will study this report and the significance of this boat pollution of the international waters on our traveling public. We have required a great many Canadian steamboats to take their water-supply from the middle of the lake in large tanks, and also to treat it by means of calcium hypochlorite.

Dr. G. H. Sumner, Des Moines, Iowa: Dr. Campbell has given us some excellent plans for the railroads to follow; but, on the other hand, it seems to me that state boards can give the public some instruction relative to the way that they should travel. Education is nothing more nor less than a bundle of habits; and Dr. Hurty has well said that you cannot hope to redeem the adult, but you may train the child. Therefore, it seems to me, that we should issue short tracts of instruction to the public relative to their habits in travel. I rode on a Chicago Great Western train not long ago. The car was filled with people and the ventilation was poor. In one portion of the car was a woman and several children. I won't attempt to describe the condition of those children, but the odors in that car were extremely unbearable. Two train officials, complained to concerning the bad air conditions, failed to perceive any need for increased ventilation. When I reached Des Moines I reported the occurrence to the railroad commissioners and received a courteous letter from them. I believe, with Dr. Hurty, we had better begin again to teach the younger generation how to keep clean, and then to help the railroad companies in their efforts to better the conditions of travel.

Dr. W. H. Sanders, Montgomery, Ala.: Dr. Campbell is undoubtedly doing a great work in his field; and I am glad to say that the corporations very generally are upholding work of this kind. One of the largest corporations in the country, with its headquarters in my state (Alabama), has within the last two years organized quite as systematic a medical force for the purpose of looking after the health conditions prevailing among their employees as may be found in any of our states; and from visits to the grounds occupied by this corporation I see very great improvement. This work will spread among the corporations all over the country. Dr. Campbell's paper should be sent to all of the large corporations in the country. I want to emphasize that the people need educating on sanitary lines as much as the managers of corporations. In formulating rules applying to railroad sanitation in my state I have made them applicable to the traveling public quite as much as to the employees. If people traveling on trains are ignorant of what is reasonably decent and clean, they ought to be required to learn.

Dr. Charles C. Browning, Los Angeles, Cal.: Some work has just been completed by Surgeon Carrington of the U. S. Public Health Service in California south of San Francisco and in Arizona, concerning the influence of the movement of tuberculous patients on themselves and the traveling public. A great deal said with regard to the danger from the tuberculous patient doubtless is true; much is founded on sentiment and not on scientific data. Surgeon Carrington has spent several years in the Southwest and has been doing very thorough work in our particular section. I presume that the report will be available through the Department of Public Health.

Dr. W. C. Rucker, Washington, D. C.: The question of railway sanitation is a question of sanitation. When you have said that, you have said all. The sanitation of a vehicle is not different from the sanitation of a house. It is merely that of a house on wheels. The attempt to surround railway sanitation with something mysterious, something which stands off by itself, is wrong. The attempt to make the railroad companies and the other transportation interests of this country the goat whenever it comes to anything sanitary is equally wrong. In enforcing the interstate quarantine regulations I have dealt with a large number of railroads; and there has never been an order, a suggestion or a comment made to those common carriers by the U. S. Public Health Service which has not been acted on favorably and immediately. The railway companies, as has been said, in their sanitary methods are in advance of the people living along the right of way. Furthermore, when they are asked to furnish an example to people living along the right of way, they are invariably willing so to do. I do not believe that much education is necessary with regard to the railway interests of this country. I do agree that we should educate the general public how to travel on railroad trains; and, in order to do that, we must educate them how to live in houses. Not until people realize that cleanliness is our great bulwark against disease, whether it be in the home, the train or the ship, will they keep their environment clean. A speaker at the surgeon-general's conference the other day put the thing very aptly. He said that regulations had been made excluding from trains the common towel, that the common drinking-cup had been abolished, and that it would not be very long until the common brush and comb were taken from the train. He said, after that the next thing will be to abolish from trains the common hog.

Dr. Charles J. Hastings, Toronto, Ont.: I would emphasize the importance of better safeguarding in transportation by water. Dr. McCullough has already drawn attention to this in his reference to the work being done by the international joint commission. We have had an excellent demonstration in Toronto of the necessity for prompt action along these lines. In 1911 we found that a large percentage of our cases of typhoid in the summer months was traceable to the boats that cross our international waters. On investigation we found that the water used was all more or less contaminated with sewage. When the order was first issued to the company to abate this nuisance forthwith, they treated it with a certain amount of indifference, I then wrote them that their boats would be tied up at the docks on their return if they did not give ample evidence that their crew and passengers were to be properly and efficiently safeguarded; this resulted in prompt action on their part. They are only permitted to take water from the center of the lake; they have installed tanks of sufficient capacity to meet their requirements for the balance of their trips. Most of these boats have been so equipped as to meet these requirements and, consequently, this source of danger has been practically eliminated. Hundreds of thousands travel annually over the international waters extending from Duluth to the mouth of the St. Lawrence, into which, by our primitive methods, we are pouring millions of tons of sewage every day.

Dr. M. P. Ravenel, Columbia, Mo.: A very excellent paper by Dr. J. O. Cobb of the Public Health Service appeared in The Journal of the American Medical Association several years ago calling attention to the fact that whether or not steamships on the Great Lakes took their water from the center of the lake, they got a certain amount of sewage into their water tanks, because the pipe through which the water is drawn opens out through the bottom of the ship, and when standing in port this pipe is filled with sewage. When the pumps are started to fill the tanks with water this sewage is first sucked up.

Dr. N. F. Campbell, Chicago: One word about education. The railroad I am connected with issues a magazine—fifteen or twenty thousand copies a month—and we have an article on sanitation in that magazine. I don't believe that water-coolers can be kept clean by cleaning them out every two weeks. They ought to be cleaned out at the end of every run. You will always find them dirty then. I have had a good deal of trouble with dumps. Railroads have a lot of waste material, and they throw it all into one place as filling material. This causes all kinds of trouble, and I have concluded that they should not do that without taking extra care about it.

LOCAL ANESTHESIA IN THE PREVENTION OF AFTER-PAIN AND SHOCK

ARTHUR E. HERTZLER, M.D.
KANSAS CITY, MO.

Immediately after a major operation under local anesthesia one is impressed by the well-being of the patient and by the diminished after-pain as compared with similar operations under narcosis. The inference that we have here the solution of the problems of after-pain and shock is easily made; but unfortunately most surgeons come to realize that these problems are not simple ones, and that local anesthesia is not alone adequate to solve them.

I. AFTER-PAIN

After operations patients begin to feel pain at various periods, depending on the anesthetic used and on such other considerations as normal differences in the regions operated on, the state of tissue at the site, and the attitude of the individual toward discomfort and pain. The duration of anesthesia by an agent used locally can be determined approximately by experiment, but in an operation such data cannot be entirely trusted because of the variable factors mentioned above.

Generally speaking, we may consider that anesthetics interrupt the propagation or perception of painful impressions, and that the amount of painful impressions originated does not vary no matter what agent is used. If local anesthesia lasts an hour or two, the total after-pain is reduced by that much. In the case of ether anesthesia, the time between the infliction of the first wound and the return of consciousness deducts from the total after-pain. In many of the published observations on after-pain, a fallacy to the discredit of ether anesthesia has been introduced from the fact that most operators use a preliminary dose of morphin with local anesthesia, but not with general. The effect of this narcotic may last after local anesthesia has worn off, but does not interfere with the clear consciousness of the patient that he has withstood the operation. For this comfortable state of mind, the local anesthesia is likely to get the credit. On the other hand, when the ether patient who has had no morphin awakens, his befuddled brain is impressed with pain impressions from the operated region. His sensitiveness is heightened, his orientation confused, and his vocabulary loosened.

If one compares a long series of patients who have been operated on for the same malady, some with local, some with general anesthesia and all with a preliminary injection of morphin, with a like series in which morphin has not been used, one finds that the difference between local and general anesthesia as to the amount of after-pain is not very great. If, now, a similar series of comparisons be made with novocain and gas, with and without morphin, one has a fair basis for comparing the different methods. Ether patients complain the most, but between gas and novocain patients there is not much difference when the duration of the novocain anesthesia is considered.

Patients who have been operated on at one time under ether anesthesia and subsequently for a similar operation under local anesthesia—as, for instance, when operated first on one side and then on the other for hernia, or for block dissections of the neck — when asked to compare the methods, declare invariably in favor of local anesthesia because they escape the ether. The difference in after-pain is seldom mentioned. In a few cases only, such as about the anus, and in the fingers and toes, is after-pain a prominent feature. If one places the two methods in this way approximately on equal grounds, one loses much of his enthusiasm for local anesthesia as a preventive of after-pain.

In considering after-pain with local anesthesia, one must consider the hyperesthesia which often occurs about the insensitive region. As I have previously pointed out elsewhere, this is an extreme hyperesthesia to touch which often lasts for days and is difficult to estimate or to control. Irritation by the end of a suture or from the sliding of a dressing may cause acute pain. Such pains are usually disregarded by the operator because he fails to comprehend them or to measure their importance. After experiments on myself I have more than once, when the bedclothes gently stroked an hyperesthetic area, sat up in bed and delivered eloquent remarks on the folly of self-experimentations. These things have received scant recognition in the literature, but they sometimes play an important part in the discomfort of the patient and must be added to the sum total of after-pain in operations under local anesthesia.

These remarks apply especially when novocain in combination with epinephrin is the local anesthetic used, because of its evanescence. There are some cases in which local anesthesia may be used with confidence to prevent after-pain. Quinin, when properly used with full consideration for the possible hyperesthetic zones, is of great value on account of the duration of its effect. In major amputations, infiltration of the exposed nerves with quinin and urea hydrochlorid relieves after-pain and its consequences with certainty. In the incision of inflamed areas on the extremities, such as felons, blocking with quinin will control the after-pain for a long time. In general it may be stated that, when all nerves leading to a part can be infiltrated with a lasting anesthetic, pain may be controlled. In regions in which nerve anastomosis is free, as about the anus, the pain is as likely to be increased as decreased by the anesthetic unless definite rules are observed. In operations for hemorrhoids, for instance, infiltration of a ring about the individual pile may be followed by exquisite pain, while infiltration directly into the pile itself will be usually followed by prolonged anesthesia. The reason for this is plain. The prolonged effect of quinin is due to the granular fibrin deposited about the nerve-endings and fibrils. Therefore, when a ring is injected about a pile, the skin is anesthetized for a long period only where there is a deposition of fibrin. The area within is anesthetized for a brief period only and when this brief period is ended hyperesthesia replaces the anesthesia, and if a ligature or suture has been placed in such an area, exquisite after-pain is the result. Sacral blocking with quinin in operations on the anoperineal region serves in most instances as an effective means of controlling postoperative pain for a long period. It is possible that such prolonged blocking of the nerves may affect the healing of the tissues.

Ford Rogers first used quinin and urea hydrochlorid purely for the control of after-pain, by injecting very painful areas during major operations under ether. For instance, if hemorrhoids are operated on at the end of an operation for other disorders, the pile is directly injected with quinin. In this way the prolonged after-pain is controlled. In major operations, generally, the nerves can be injected before they are severed. In order that such injections shall relieve the after-pain, however, they must be done with the same care and in the same manner as though the operation were being done under local anesthesia.

The greatest service of local anesthesia in the prevention of after-pain has been in teaching the operator which tissues are painful. After-pain usually results from the incision in the skin, which produces a burning or stinging sensation lasting some hours, and from the ligation of sensitive parts, which produces an intense burning or throbbing pain lasting from twenty-four to seventy-two hours. If, therefore, one avoids placing constrictions about painful tissues, there will be relatively little pain. This applies to stitching of such viscera as the gall-bladder, folding of round ligaments, ligation of nerves and particularly tight suturing of skin.

Fortunately, tissues that require firm suturing are insensitive and sensitive tissues do not require firm suturing. Fascia has no nerves, and if in the course of an operation requiring the opening of the abdomen the prefascial fatty tissue is elevated, the fascia proper is without pain. The parietal peritoneum must be coapted with the greatest gentleness, with fine sutures, using just sufficient force to bring it into contact. The fascia, when freed from the nerve-bearing fatty layer, may be sutured together firmly and under such tension as will relieve the strain on the peritoneal sutures. This line of sutures is the only one of consequence in securing firm union, a fact abundantly attested to in the various operations for hernia. If vessels requiring ligation have been severed the accompanying nerves must not be included in the ligature. The importance of this can be best studied in ligating the superficial branches of the deep epigastric vessels in operations for hernia. If the vessels are picked up before they are cut they may be ligated without pain. This cannot be done with a heavy forceps, but with delicate instruments small vessels may be readily picked up without any surrounding nerve-containing tissue. Even slight constriction of nerves becomes painful when the effect of the anesthetic passes off.

From the foregoing it would seem that by the use of quinin and urea hydrochlorid, after-pain could be controlled with certainty. Unfortunately, this drug by its mode of action brings with it its own limitations. The prolonged anesthesia is due to the deposition of granular fibrin (often erroneously referred to as edema). Anesthesia lasts until this fibrin is absorbed. The amount of fibrin formed depends on the strength of the solution, the length of time it acts, and the character of the tissues injected. Moderate injection of the skin produces a prolonged certain anesthesia. An excess produces a retardation of the healing of the wound. In loose tissue, as of the neck and preperitoneum and in muscle, exudate is excessive, and an indurated mass results which may disturb the line of suture. In the peritoneum and in the neck the thickened masses may cause the patient some apprehension, and about the anus they give an uncomfortable feeling of fulness. It is only in conditions in which prompt healing is not imperative that quinin can be used to secure its fullest effect as an agent to control after-pain. These conditions are found in anal operations and in the opening of abscesses, particularly appendiceal, pleural and pulmonary. The control of pain is perfect in nerves exposed during the course of operations. Experience alone enables the operator to approximate the effect he desires to produce. Imperfect as it is, however, quinin alone at the present time offers any hope for the control of after-pain.

With this, I believe, rests the problem of after-pain. Local anesthesia may teach us to perfect our technic so that after-pain is reduced to a minimum, but it cannot prevent it. The cheerful squirting of a few syringefuls of local anesthetic solution in the neighborhood of a carelessly handled wound is entirely futile. The skilled operator who by study or intuition has learned delicacy of manipulation is able to decrease greatly the after-discomfort incident to the operation. Local anesthesia contributes to well-being after operation, not chiefly by preventing after-pain at the seat of operation, but by eliminating the effects of ether. Schlesinger is no doubt speaking from experience when he expresses the opinion that we are just beginning our studies of the use of local anesthesia in the amelioration of after-pain.

II. SHOCK

The use of local anesthetics prevents the transmission of impulses to the brain during the time of operation and for a variable period afterward. What effect the transmission of the pain during the operation may have on the subsequent well-being of the patient is not easy to estimate. Intense after-pain, as after unskilful ligation of hemorrhoids, or tight sutures in other sensitive tissues, may produce intense pain for prolonged periods, but shock does not follow. On the other hand, shock may follow operations on regions not particularly sensitive.

The kind and source of the pain must, therefore, be a factor in the production of shock; but because of the close association of the various types of nerves the importance of painful impulses in the production of shock is not definitely known. We do not know what shock is; we know only something of the conditions under which it occurs. It is difficult, therefore, to estimate the value of local anesthesia in the prevention of shock. Besides inhibiting pain the anesthetic may inhibit afferent impulses which are not perceived as pain, but which produce the state we call shock. If this be true local anesthesia might be a factor in the prevention of shock or might even prevent it entirely.

Enthusiasts have, in fact, stated that with local anesthesia there is no shock. This is not true, and as the experience of the enthusiastic advocate of local anesthesia increases, his statements become more conservative. There can be no doubt that shock is diminished, but whether this is due to the merits of local anesthesia or to relief from the ill effect of general anesthesia is still a question. If big operations are done under local anesthesia, even when there is no pain, one can now and then feel his patient wilt under him. This may occur without the patient suffering pain or mental agitation or loss of blood, and when intoxication from the anesthetic used is not likely.

This may be best observed in block dissections of the neck for carcinoma of the lip and tongue. A case in point may be cited. The patient (man aged 56) came to the table perfectly calm. The operation proceeded without pain. Everything was being removed but the common and internal carotid, the sympathetic and vagus. As efforts were being made to get a ligature on the jugular high up, the patient began to lie flatter on the table. When asked if he was feeling it, he replied, "No, not a bit," but came back with the question, "Are you about through?" Is he receiving impulses from the field of operation not interpreted in terms of pain? Is it a feeling of anxious apprehension and if so would gas at this point save him? Anticipation of this state by the use of gas in the latter stages of the operation does not prevent the collapse. I believe his apprehension is due to impulses he got which were not fully blocked off—perhaps a tugging on the jugular within the skull. At least it occurs in individuals who deny that they experienced either pain or fear.

The occurrence of shock is a rare thing outside of traumatic accidents (whether or not produced by surgeons). When shock does occur in the hands of a competent operator it affects patients suffering from metabolic disturbances or from lesions which make extensive traumatism necessary, such as deeply seated adherent tumors, the removal of which is attended by injury to sensitive tissue. Of course it is difficult to estimate accurately the mental state of the patient. We can only judge by what he tells us and by what we can see. Patients who do not admit pain and seem to suffer no mental agitation sometimes return to bed weary and in perspiration. It has always seemed to me that the removal of tissues abundantly supplied by sympathetic nerves is more apt to be followed by this condition which we may call mild shock. In laparotomies under local anesthesia, explorations about the duodenum and gall-bladder or pressure on the kidney often make the patient look pale and weaken. When asked if it is causing pain he replies, "No, but it makes me feel sick." Unfortunately, regions most abundantly supplied by sympathetic nerves have not as yet been successfully blocked with local anesthetics and it is useless to speculate on what would happen if we could. True, many operators have attempted blocking of the rami communicantes, but with uncertain success. We are compelled to admit, therefore, that with respect to the shock-potent regions near the solar and sacral plexuses we have as yet no information which will enable us to determine how much could be done to prevent shock if we could block them off.

In desperate operations in which shock is to be expected, we are forced to resort to general anesthesia at least for that portion most likely to produce shock, namely that portion concerned with irritation of sympathetic nerves.

In the prevention of shock local anesthesia stands in much the same relation that it does in the control of after-pain. It eliminates the ether. Ether is not only unpleasant to the patient, but it injures and in some instances endangers him. No attempt will be made here to study the chemical effects of ether. I may say, in passing, that it is a lipoid solvent and dissolves out the cement substance between the cells to which it has access. These changes resemble those due to physical fatigue and perhaps to stimulation through the nerves. The profession is slow to convict a recognized procedure of danger or deficiency until it is sure it can get along without it. It is questionable if we should have discovered chloroform liver necrosis if we had not had ether. My own studies on the chemical effect of ether on living tissue convince me that ether is capable of harm to a degree second only to chloroform. In the vast majority we operate on patients under local anesthesia in order to save the discomforts of ether; in some instances we employ it to avoid the dangers of ether. We use local anesthesia, therefore, because it adds to the comfort and safety of the patient—both of which are attained chiefly by the elimination of ether.

Local anesthesia fails us in the essential steps in those operations which are attended by shock. Apprehension for the operation has much to do with the resistance of the patient, we admit, and hence, with the result of the operation. Sometimes, back of all that causes both apprehension and resistance, there is such a factor as constitutional disease. The effect of fear may be eliminated in some patients by local anesthesia, but it is eliminated in a greater number by the assurance that they need not go to sleep. It is the fear of that sleep that injures the patient. Nothing does so much to tranquilize a patient as the assurance that ether will not be necessary. In the desperate cases we cannot give this assurance, but it helps somewhat to say that we will go as far as we can and then give a little gas (and then ether *voce dulci*). In this way we shorten or avoid the ether, which is the essential thing. Also we must be gentle and considerate in our demeanor and in our operative technic.

Too little attention has been paid to the preparation of the patient. A case in point may illustrate this. An exceedingly nervous patient with a goiter was told that it could be removed under local anesthesia. She became much agitated and declared that she wanted to hear nothing of local anesthesia. She wanted to be asleep and know nothing about it. The anesthesia was not mentioned again. She was put to bed and told to let me know when she was ready for the operation. She was placed on bromids and after five days informed me that she was sufficiently rested to have the operation the following day. She was given 10 grains of veronal in the evening. When visited in the morning she declared she felt fine. She received morphin 1/8 grain, atropin 1/150 grain. After she was placed on the table she was told that local anesthesia would be proceeded with. She made no comment and there was not a particle of trouble with the operation.

Many who believe they are following the anoci-association method of Dr. Crile content themselves with a little aimless squirting of local anesthetic into the patient's skin and a little more into a perfectly nerveless fascia. They begin the operation before the anesthetic has had time to act. They overlook the skill and gentleness and the avoidance of ether which the originator brings to the method. The imitator is perhaps not alone to blame, for Dr. Crile himself evinces a greater faith and achieves better results than anyone else who is experienced with local anesthetics. After several years' study of the action of quinin both clinically and histochemically I am unable to understand Dr. Crile's faith. What quinin will achieve in the peritoneal fascia, aside from making the healing of the peritoneum uncertain, was not ascertained by my experiments. Without giving details of technic he states in describing his operation for thyroidectomy: "Before the wound is closed the entire raw field is infiltrated in every part with quinin and urea hydrochlorid." The raw field, in so far as infiltration is permissible (excluding the trachea, vessels and vagus nerve), is composed largely of muscle. This tissue causes no after-pain and when infiltrated with quinin exudes a reddish fluid which does not coagulate and tends to prevent wound-healing for a long time. These facts have caused me to avoid the use of quinin in thyroidectomies.

All this is looking only at the simpler phases. In those operations in which shock is likely to follow, local blocking has as yet offered nothing. The nerve distribution to the viscera is such that a deposit of anesthetic solution in their vicinity is uncertain and in the presence of adhesions and inflammatory exudates an effect on the nerves is out of question. In those instances in which it is applicable, a wait of from fifteen to twenty minutes is required before the action is complete. This delay is not without moment. True, Dr. Crile seeks to hasten its action by pressing on the area infiltrated, which, theoretically, should delay its action.

When operating with local anesthesia while the patient is asleep with gas, the operator is unable to determine whether or not the tissue is anesthetized. Bloodgood has called attention to this point. Unless the infiltration is perfect it misses its point. The gas is to serve only to prevent the patient from knowing that he is being operated on.

Dr. Crile, in speaking of the elimination of shock, admits that the patient does not always escape a dangerous depression. If, however, this depression results fatally it makes little difference whether or not there are changes in the brain-cells. By emphasizing the changes in the brain-cells, Crile removes from the term "shock" its purely clinical meaning, and substitutes an unproved histologic hypothesis. We know, as yet, too little about the termination of the nerves transmitting pain to be sure that changes found in a given nerve-cell are due to such transmitted stimuli.

Nor has an unquestionable proof of the relation of nerve-cell changes to the clinical picture called shock, yet been advanced. Local anesthesia to date has eliminated shock from those operations which can be done under its influence. In the larger operations, however, except those about the neck for carcinoma and in carcinoma of the rectum, it has not, as yet, been fully successful. In many operations, by reducing the period of anesthesia, it has reduced the tax on the patient's resistance. In the grave abdominal operations it has, so far, contributed but little. The visceral nerves, when irritated by inflammation or by the invasion of new growths, are exceedingly sensitive, and no safe method has yet been devised to prevent the transmission of these impulses to the brain. In these cases all that local anesthesia can do is to make the abdominal wall insensitive, and it seems likely that this is but a small factor in the production of shock. The prevention of shock in these cases must depend on the deftness of the operator, and his ability to judge conditions correctly in order that he may manage them with the least traumatism, in the shortest time, with the least loss of blood.

DISCOVERY OF BACTERIUM TULARENSE IN WILD RABBITS AND THE DANGER OF ITS TRANSFER TO MAN

PRELIMINARY NOTE *

WILLIAM B. WHERRY, M.D.
AND
B. H. LAMB
CINCINNATI

We wish to record our recent demonstration of *Bacterium tularense* in a fatal epizootic among wild rabbits, and to emphasize again the fact that this disease is probably widely distributed among rodents and probably transferred to man more frequently than heretofore recorded. We have demonstrated this virus in two severe cases of conjunctivitis accompanied by lymphadenitis, high fever and marked prostration. The first case of human infection has already been reported by us.[1] This case came under the care of Dr. Derrick T. Vail[2] of Cincinnati, who has reported the details of the clinical course of this case. The second case is still under the care of Dr. Robert Sattler of Cincinnati, and will be reported by him.

McCoy and Chapin first described the disease in the California ground squirrel. Naturally we have been anxious to find the source of human infection in this locality. Through the kindly cooperation of Dr. J. H. Landis, Health Officer of Cincinnati, we have been able to do so. Dr. Landis heard that rabbits were dying in large numbers in the neighborhood of Vevay, Ind. (Switzerland County). Two men were sent down, November 12, to investigate the rumor. They could not find any evidence of extensive mortality among rabbits, but they shot three and found two dead on the M. farm about 6 miles from Vevay. These were dissected, November 13, and both of those found dead were proved to be infected with *B. tularense.*

Rabbit 1.—The external appearances were normal, excepting for the presence of many fly larvae in the nose and mouth and on the skin. None of these had penetrated the tissues, so it is presumable that the rabbit was found soon after it died. On dissection the subcutaneous tissues showed some injection.

There were many small irregular areas of hemorrhage into the skin covering the posterior aspect of the hind legs and rumps. The cervical glands were congested and firm on section. The spleen was a deep blue-black and about four times the normal size and speckled all over with minute whitish foci of necrosis. The liver was congested and also showed numerous foci of necrosis. The lungs appeared normal excepting for a few patchy areas of consolidation of a deep brownish-red. The peritoneal cavity was full of a hemoglobin-tinged serous exudate.

Smears from the spleen stained with anilin (Hoffman's violet) showed numerous irregular, coccoid, encapsulated bodies resembling the involution forms of *B. tularense.*

Guinea-Pig 1 inoculated subcutaneously with an emulsion of the spleen of Rabbit 1 was chloroformed when dying on the third day thereafter. It showed the typical lesions which have been described by McCoy and Chapin, and by us.[1] *B. tularense* was isolated from the spleen of this guinea-pig on a slant of coagulated egg-yolk, while no growth appeared on control slants of plain nutrient agar and rabbit's blood agar.

Rabbit 2.—This animal showed marked post-mortem decomposition and was badly fly-blown. However, minute whitish foci of necrosis could be made out on the soft enlarged spleen and on the liver. An enlarged axillary gland was emulsified and injected subcutaneously into Guinea-Pig 3. This pig died in three and a half days, showing the typical lesions of infection with *B. tularense.*

We are anxious to help physicians in the discovery of further cases in man. It may be that physicians in country districts who have not the facilities for bacteriologic study may be willing to send us material from severe cases of conjunctivitis or lymphadenitis in man. These may well prove to be cases of this disease when there is a history of having shot or handled rabbits, squirrels or ground squirrels. A cotton swab, soaked in such exudations as can be reached, mailed to us by special delivery and accompanied by a note concerning the nature of the case will be reported on as soon as possible.

---

Conservation in Evolution.—Organisms have evolved by a trial and error method; they experiment organically, instinctively, and intelligently; above all, perhaps, in the mysterious antenatal life of the germ cells they experiment in self-expression—just as water vapour does in snowflakes, but far more subtly. What are called variations and mutations in biological language are the organism's experiments in self-expression, and these are the raw materials of progress. The organism proves all things, but the other side is that it holds fast that which is good. Great gains once made are not held lightly. Species become extinct and races perish, but important organic inventions are carried on by some collateral lineage. It was probably some ribbon worm that first manufactured hemoglobin—the all-important red pigment of the blood. Many backboneless animals of higher degree on different lines of evolution have not got it, but the invention was too good to lose; and everyone knows that it was retained on collateral lines, and that all backboned animals from fishes onward have red blood. Or again, the most primitive and in a way most puzzling kind of locomotion is that of the ameba gliding in the pond. Is it not a most suggestive fact that our health from day to day and the development of our nervous system are absolutely dependent on this self-same ameboid movement?—J. Arthur Thomson, *Brit. Med. Jour.*

Therapeutics

PREVENTION IS GREATER THAN CURE

(Continued from page 1953)

X

MEDICAL INSPECTION OF SCHOOLCHILDREN

The importance of this subject is evident when it is estimated that 70 per cent. of deaths in the United States are due to contagion, that the vast majority of such contagion originates in schools and that, annually, about 11,000 die of scarlet fever, about 10,000 of whooping-cough, and about 9,000 of measles.

Some considerations in the prevention of disease acquired in school are as follows:

It is estimated that each pupil should have 15 square feet of floor space and 200 cubic feet of air space. Each schoolroom should be about 30 feet long, 25 feet wide, and 13 feet high, and should accommodate not more than fifty children. Allport states that the temperature should be about 68 F., and the humidity between 60 and 70. The thermometer should hang where it will tell the truth, and the best region with this object in view is on a bracket on the inner wall about 4 feet from the floor.

The sanitary measures require proper plumbing, proper drinking facilities, proper towels, sterilization of pencils, books, etc., and antiseptic cleaning of schoolrooms. Safety requires good fire escapes and fire drills.

Medical inspection was started systematically in Belgium, and is now being gradually adopted by many of the European countries and by a large number of the cities of the United States. Perhaps more than 500 of our cities now require medical inspection. Such inspection has been shown to be a necessity and not a luxury. It has been shown that contagious diseases are more prevalent during the months when schools are in session than when there is vacation; therefore if civic and state governments compel the attendance of children at school, they are bound not to subject the pupils to an increased danger of disease and death. Hence medical inspection should be required by state laws, and about half of the states have already passed such laws. It should not be left to the petty decision of towns or cities, although the larger cities have long been pioneers in this work.

This article will not attempt to deal with the question of salaries or the best method of managing the work cooperatively with the boards of health and school boards. The medical inspectors should be selected for their ability and interest in such work, and should be paid adequately. Also, they should not be subject to removal by political changes, if their work is satisfactory.

The results of the inspection for contagion or infection should be noted on a filing card, which record should be filed separately from the cards previously described in the "physical examination," although a cross-reference on the physical examination card should be made. Later, on this contagious card, there should be noted the results of treatment and the outcome of the case.

It is not suggested or advised that there be two sets of medical men examining and inspecting in schools, but it is urged that the two kinds of work are distinct, that the latter, medical inspection, is essential, and that as much of the former, physical examinations, should be undertaken as is possible. The work can be, at least in small districts, splendidly combined.

The same care should be exercised by the medical inspector not to overstep his rights, but to refer all cases back to the parents and the family physician, as was urged in the physical examination discussion. The trained nurse of each school or each district should follow up each case of infection sufficiently to determine that the child is being properly cared for, and that the infection of others is prevented. In all cases in which a complete examination is desirable the consent of the parents should be obtained beforehand. In all cases where any examinations of girls are made, the trained nurse should be present. A private examining room in each school will facilitate and minimize the objection to such examinations.

A FEW SUGGESTIONS FOR THE MEDICAL INSPECTOR

1. The medical inspector should note the vaccination mark (present, absent, character).
2. He should note skin eruptions.
3. He should look for evidence of body or head lice.
4. He should be on the lookout for trachoma (which in some regions is of frequent occurrence).
5. The inspector should make a careful examination of every child found by the teacher or trained nurse with eruption, sore throat, a suspicious cough, or fever.
6. He should examine all other children who are in immediate contact with the one who is ill or is found to have a contagious disease.
7. He should examine all other children who live in the same house as the one affected and who are attending school.
8. He should cooperate with the board of health to determine when a cured child should return, and when suspects should be subjected to, and when they should be released from quarantine.
9. When there is no physical examination of all children in a school as previously outlined, the inspector should make as much of an examination of apparently unhealthy children as possible. The important objects to be determined are: the condition of the teeth, nose, throat, eyes, ears, spine, feet, ankles, glands, heart, lungs, nutrition, mental condition, etc.

NUTRITION

Medical inspection should really be medical supervision at least with the aid of the trained nurse, and a great problem of child health and of prevention of disease is that of nutrition. Underfed children are in goodly numbers, as shown by such statistics as are available, and for such the question of the diet at home is important, especially the breakfast. The homes and diet of all ill-nourished children should be investigated by the trained nurse. The value of the school luncheon is unquestionable; however, its advisability must be determined by each community, but the actually underfed children must in some manner be provided with good food. There is no possible excuse for compelling a child to study who is receiving insufficient food.

EYES

A very large percentage of children of school age are found to have defective eyes. Such defects being discovered, how many receive the proper glasses, and then how many keep their glasses properly adjusted, and how many have reexamination as often as they should (such examination should be once a year) to determine the changes that will occur? It is readily seen that the eye question is a serious one.

As many children as possible, who have been found to have defective eyes and eye-strain, should be sent by their parents to oculists of repute, and the danger of consulting opticians and so-called optometrists and department store eye clerks should be explained on a printed slip issued by the board of health or the school board. This paper should also urge that the child have spectacles with large sized lenses and rigid, light weight, inexpensive frames. There is no other method to equip an astigmatic eye properly, especially in children. All other frames, for a child, are a delusion and a snare. If a family can afford it, "dress up" gold or gold-filled frames may be had as an extra pair. Each child with glasses should have a good case for them, and in all rough games the glasses should be taken off and deposited in these cases and the cases placed in a safe spot. This detail may seem superfluous, but it is all-important.

If the visiting nurse ascertains that the parents are unable to pay for a skilled oculist's examination, or for the lenses, then the child should be sent to a regularly appointed oculist who receives a small salary for such services. Later the prescription for glasses should be taken to a regularly appointed optician or one of several who have contracted at minimum rates for such cases. Dispensary service for determining the correct refraction of a child's eyes for his life work is unsatisfactory and generally unavoidably bad. A child had better have no glasses at all than to have incorrect ones. Neither should it be expected that the oculist can devote time and science, unpaid, to such a nerve-tiring work as determining the proper glasses for children. They are willing to do emergency and eye disease work for the poor gratis, but eye refraction work should be paid for. Why should a community demand that a child go to school and then demand that some member of the community, without pay, make the child fit to go to school? On the other hand, the correction of eye-strain in children not only causes them to learn with more ease, but prevents eye defects that may mean untold suffering for years after. The migraine sufferers will certify to the correctness of this statement.

TOBACCO: ALCOHOL

There is no question that during the teaching of school hygiene, during the study of physiology in school, and during the brief description of the action of, and the antidotes to, the more common poisons, the baneful effects of tobacco and alcohol should be honestly shown. It is of no more advantage to disseminate lies in regard to these narcotics and habit-forming substances than to teach any other branch of knowledge incorrectly. The truth is bad enough.

It is inexcusable for parents to give young children alcohol, but it is not wise to teach children that because their parents occasionally partake of a glass of beer or wine, they are condemned to perdition physically and morally. The higher standards of communities and the proper supervision of all places that sell liquor that is to be drunk on the premises will soon make overdrinking unusual except in the diseased. The moderate use of alcohol by adults must for some time be a matter for individual decision. Youth and those under age should not take alcohol in any form, not even tinctures or caffein stimulants at the soda-water fountains.

Much more serious for the many among our young boys and young men is the overuse of tobacco. Where one young man uses alcohol perhaps twenty use tobacco. Cigaret smoking in young boys is tolerated in some preparatory schools, and even in some public high schools. In fact, a large number of young men under 21 years of age smoke excessively and to their detriment mentally and physically.

The symptoms and signs of oversmoking, the impaired chest and lung development, the impaired heart action, the impaired nutrition, injured nerves and weakened muscles are all matters of medical knowledge. These vary only in degree in young boys who overuse tobacco, and are all more or less in evidence sooner or later. Emphatically, growing boys should not be allowed to smoke, even if their fathers and teachers do.

(To be continued)

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

ANTIRABIC VACCINE (See N. N. R., 1914, p. 269).
Laboratory of W. T. McDougall, Kansas City, Kan.

Pasteur Antirabic Vaccine.—The virus is prepared according to the method of the Hygienic Laboratory, Washington, D. C. An amount of the dried cord, sufficient for one dose, is emulsified in 50 per cent. glycerin accompanied by a syringe containing sterile physiologic salt solution for further dilution at the time of administration. A dose is sent daily by mail in a vacuum container. The treatment consists of twenty-one or twenty-five doses, according to the severity of the wound.

SOLUTION PITUITARY EXTRACT.—An aqueous sterile solution of a purified extract of the posterior (infundibular) lobe of the pituitary gland of the ox, sterilized by addition of camphor water and 0.5 per cent. of boric acid. Each cubic centimeter is assayed to correspond in strength to 0.2 Gm. of the fresh posterior lobe.

Actions and Uses.—Solution pituitary extract stimulates the unstriped muscle, especially affecting the arteries, spleen, uterus and intestinal muscles.

Pituitary extract is used (by hypodermic or intramuscular injection) mainly to stimulate the uterine contractions in labor. It is also employed in pareses of the intestines and bladder, especially postoperative. It has been tried as a circulatory stimulant and diuretic but is probably of little if any use for these purposes.

This remedy should not be injected during the first stage of labor, because if the os uteri is not fully open the energetic contractions may cause a rupture of the uterus.

Dosage.—The average adult dose is 1 Cc.

Manufactured by H. K. Mulford Co., Philadelphia. No U. S. patent or trade-mark.

Ampules Solution Pituitary Extract.—Each ampule contains solution pituitary extract 1 Cc.

Fresh posterior lobes of the pituitary gland of the ox are ground, dried, defatted, extracted with acidulated water, purified by heating to coagulate inactive protein matter, and the solution so obtained assayed by the isolated uterus method (*Jour. Am. Pharm. Assn.*, June, 1914, p. 808). After adjustment to proper strength it is sealed in ampules and sterilized by heat.

Solution pituitary extract is an almost colorless liquid having a faint odor of camphor.

VOLUNTARY ACCELERATION OF THE PULSE-RATE

It is doubtless true in the case of most persons that they are unable to render many of their important physiologic functions subject to the action of the will. The performances of the alimentary tract proceed without our knowledge and independent of any volition on our part. The heart carries on its duties in the maintenance of the circulation with persistent efficiency and without interruption. The contraction of the cardiac organ is modified by impulses that come to it from within and without; but these regulatory impressions are rarely the direct product of the human will.

There are persons, though they seem to be exceptional and few in number, who can exercise a voluntary regulation of the heart-beat. Tarchanoff,[1] in 1885, observed a medical student who could alter his pulse-rate at will. He found that men with this faculty had generally an exceptional control over their skeletal muscles; for example, they could bend the third joint of a finger independently of the other joints, or contract the platysma muscle, or certain individual groups of the muscles of the arm and neck. In the case observed by Pease,[2] the subject could voluntarily accelerate his pulse-rate as much as twenty-seven beats per minute and likewise exhibit the control over other muscle groups just referred to.

It is, of course, a well-known fact that the cardioregulatory centers can be affected by stimulation of afferent nerves, and can be influenced experimentally from the cerebrum or by the action of the blood on the centers. The frequency of the pulse can be altered by psychic and emotional states. Thus in many persons it may be slowed by directing attention to the contemplation of painful subjects. The mere physical examination on the part of a physician may give rise to a familiar acceleration of the pulse. In the case of an individual counting his own pulse its frequency may even become diminished. In conditions of hypnotism, the pulse-rate has been observed to change markedly under the influence of suggestion. All such instances, however, belong in quite a different category from the direct voluntary acceleration of the heart-beat in man to which we have particularly referred.

What is probably the most carefully recorded illustration of this anomalous behavior has been described by Koehler, a student in the physiologic institute at Strassburg, who is able to increase his pulse-rate as much as twenty beats per minute by the impulse of his will.[3] He remarks that the mere concentration of his attention on the activity of the heart is not of itself sufficient to produce the acceleration. The mere "will" to increase the pulse-rate must be accompanied by an indescribable mental effort which is comparable with that whereby we provoke a contraction of our voluntary musculature—a voluntary effort, it might be designated. In order to accomplish the feat it is essential, in Koehler's case, to avoid the distractions which noises, unusual sights and similar stimuli playing on the sense organs may create. Although he can almost invariably succeed in evoking the acceleration, he is utterly unable to induce a slowing of the pulse-rate by an act of will. In his case there is reported to be a lack of the peculiar temperament or neuromuscular make-up which has been described for others. During the voluntary acceleration of the heart-beat no unusual physiologic or mental peculiarities appear. There is no blushing or sweating which might suggest a greatly altered vasomotor response. Only when extreme effort to accelerate is attempted do special muscle groups show any subjection to the peculiar voluntary control. At these unusual moments of most intense "willing," slight shivering or trembling of muscles in the neck or arms may be exhibited. A striking phenomenon is the evident dilation of the pupils. A sensation of indefinable discomfort and intrathoracic pressure makes itself felt; but practice in the voluntary acceleration — a performance against which Tarchanoff uttered a warning on account of its supposed danger—makes these symptoms less emphasized.

The mere description of an unusual physiologic or anatomic phenomenon has a restricted value unless it can serve in some way to enrich our knowledge of normal or abnormal function. A careful clinical examination of Koehler by Wenckebach of Strassburg failed to disclose any unusual condition of the heart at any time. There were no irregularities of the beat or changes in the working capacity of the heart. The acceleration of the pulse was always accompanied by changes in respiration and increased blood-pressure, but the latter is not to be looked on as a cause of the acceleration. Indeed, a primary rise in blood-pressure is much more likely to result in a decrease in pulse-rate, as a general rule.

---

[2] Pease: Boston Med. and Surg. Jour., 1889, cxx, 525. Another case was observed by Van der Velde: Arch. f. d. ges. Physiol., 1897, lxvi, 232.

[3] Koehler, M.: Ueber die willkürliche Beschleunigung des Herzschlages beim Menschen, Arch. f. d. ges. Physiol., 1914, clviii, 579.

All of the cases of rapid heart action of other than reflex origin raise the question of the immediate cause of the acceleration. Is it due to a diminution of the tonic activity usually exerted by the inhibitory vagi over the heart, or is it attributable to a direct action on the centers of the accelerator nerves? The earliest careful investigator[1] of the phenomenon of increase in heart-rate in man drew the conclusion that the voluntary acceleration was due to the accelerator nerves. In an exhaustive study of the acceleration of the mammalian heart, Reid Hunt[4] came to the conclusion that the evidence for this view is entirely inconclusive. He is inclined to think that the weight of the evidence is rather in favor of the existence of a diminished tonus of the vagi in these cases. According to Hunt, the most important function of the accelerators appears to be connected with their tonic activity; and almost all cases of rapid heart action seem to be due to a diminution of the tonic activity of the cardio-inhibitory center. Koehler, on the other hand, is inclined to place the emphasis on the participation of accelerator nerves, the stimulation of which he looks on as the essential factor in the genesis of voluntary rapid heart action. The contributory influence of a diminished vagus activity is admitted.

THE FLIGHT OF FLIES

One of the problems that has arisen in connection with the part played by insects as carriers of disease[1] concerns the distance which they may be able to travel from one locality to another. This has frequently been considered in this country in connection with mosquitoes which are responsible for the prevalence of malaria. With their breeding-places known, it has become desirable in some cases to ascertain what the range of their activities might be in respect to the territory which can be covered by insects so small as are the blood-sucking *Diptera*. It has been learned in this connection that some of the mosquitoes which inhabit salt marshes near the seacoast may be found inland at a distance as great as three miles.

Far less appears to be known with regard to the migrations of the common house-fly, *Musca domestica*, an insect that has been charged with responsibility for the spread of typhoid fever and other infectious diseases. A series of studies conducted in Cambridge, England, on the range of the flight of flies of this species has been made the subject of a report to the Local Government Board on Public Health and Medical Subjects.[2] Upward of 25,000 flies were liberated, under various meteorologic conditions, from the medical buildings at Cambridge. Of these insects, colored for identification, 191 were recovered at one or other of about fifty observation stations employed for their recovery. The results showed that house-flies tend to travel either against or across the wind. The actual direction followed may be determined either directly and by the action of the wind, or indirectly owing to the flies being attracted by any odors it may convey from a source of food. A point in favor of this supposition is the nature of the station at which flies were recovered after they had traveled any distance. These comprised a butcher's shop, public houses and a restaurant, all of which gave off odors that are notoriously attractive to flies. The chief conditions favoring the dispersal of flies are fine weather and a warm temperature. The nature of the locality is another considerable factor, because in towns flies do not travel as far as in open country, probably due to the food and shelter afforded by the houses. With regard to the altitude of the point of liberation, flies set free from the roof tended to disperse slightly better than those liberated from the ground, but the differences are not very considerable. It has been observed, with regard to the vertical flight of the house-fly, that it may mount almost directly upward to a height of forty-five feet or more. The time of day appears to influence the dispersal of the insects, as, apparently, when set free in the afternoon they do not scatter so well as when liberated in the morning.

The maximum flight observed in the thickly housed localities in Cambridge was about a quarter of a mile. In one case, where a part of the distance was across open fenland, a flight of 770 yards was noted. In experiments conducted in Cook County, Illinois, by S. A. Forbes, flies were trapped and, after being sprayed with a chemical solution for recognition, were liberated from a hospital in that district. They too were recovered at distances ranging up to a quarter of a mile from the point of liberation.[3] It appears most likely that the distance flies may travel to reach dwellings is controlled by circumstances. Almost any reasonable distance may be covered by the fly under compulsion to reach food and shelter.

It has been stated that house-flies, like other insects, exhibit color preferences. Thus it is reported that a French observer, having noticed that flies did not rest on walls covered with blue paper, blue-washed the walls of his milk house and found that insects did not visit them. A recent statistical study of the behavior of the insects in this respect has failed to bring evidence that the flies display any marked color preference.[4] Therefore it seems unlikely that the adoption of any particular color for walls will have any effect on the numbers of flies entering.

MEDICAL HISTORY IN THE MEDICAL CURRICULUM

At a meeting of the Königsberg Society of Scientific Medicine, May 18, Prof. Egbert Braatz,[1] who holds the chair of surgery in the Königsberg Faculty, indulged in sundry well-timed lucubrations on the decline of historical studies in medical education. As we can better understand the function of an organ if we know its embryology, which knowledge has, in itself, a history of its own, so, he points out, the real significance of many ideas and expressions current in modern medicine would be more clearly apprehended if we understood their remote origins. Not only does the interest in the history of medicine vanish day by day, he laments, but the swarm of teachers of the earlier type, who taught the subject as a distinct discipline, has also entirely disappeared. The reason is that the older universities taught the universal relationship of all the sciences, so that an old-time professor, who took nearly all medical knowledge for his province, usually "holding down" several chairs at once, was naturally in position to study and write on medical history. Nowadays medical science is split up into a large number of separate disciplines and specialties, to master any one of which is a sufficient life study for the average individual man. Hence, the specialist knows only the history of his specialty and seldom goes outside it. Furthermore, Braatz argues, the young student cannot, in the nature of things, have any interest in the history of a subject so vast that, on taking his degree, he has only just begun to learn it. It is idle to set final examinations in medical history when no adequate instruction can be given without impinging on studies of more immediate and practical moment. To obviate this, Braatz prefaces his own lectures with a sketch of the actual state of knowledge of the subject in hand, in order to close with its history. To this end, especially striking themes are always chosen. In some of the discourses introductory to the semester, a short general historical introduction is given. As an example of the practical value of his method, Braatz cites one of his lectures, "On the Treatment of Mammary Tumors," in which the ebb and flow of the different theories bearing on the unsolvable cancer problem through the ages is considered.

In discussing Braatz' paper, Prof. Carl Kaiserling, director of the Pathological Institute, states that the author opens an old wound, painful to all. Instruction in medical history is usually confided *not to* a specialist in the subject, but to a docent in some other branch, such as pathologic anatomy. To teach such a subject as pathology in all its theoretical and practical bearings is all that a modern professor can do. Who has time to study medical history as a modern should know it? It seems right and proper that our "historical sense" should be concentrated on the modern aspects of any subject. Who can even engage to keep up with the modern literature, when there are almost as many periodicals as days in the year? Historical interest in a subject can be aroused only when the latter has been thoroughly mastered in its present aspects. Hence, the study has to be postponed until the end of the student's course, or even after he has entered on the practical business of his life. The young student would undoubtedly be hindered by the introduction of prosy historical lectures at the beginning of his course. Kaiserling approves of Braatz' method, because by it, the instructor intertwines historical matter with his special subject.[2] Much of this might be connected with etymology, the bugbear of the beginner, only, alas, there are teachers as well as students who know no Greek. In further discussion of the paper, Professor Kisskalt opines that the history of epidemiology, as relating to the unsolved problems connected with the appearance and disappearance of infectious diseases, would be of a special interest, as also the history of errors in medicine. Professor Friedreich, of the University Clinic, testifies that he has aroused enthusiasm in his students by bringing historical matter directly into his clinical demonstrations.

We cannot too warmly commend the foregoing as the best method of teaching medical history in the student's curriculum. The history of ancient medicine is a dull subject in itself; the modern period, from the work of Vesalius and Harvey on, is the most inspiring, as Kaiserling hints, and long-winded lectures, by no matter what authority, would only crowd the medical course still further with material which could not be assimilated.

Probably the best lectures of the kind delivered in this country were those of the late Dr. J. S. Billings on medical history in relation to medical education, which were delivered at the Johns Hopkins University in connection with the proposed building of its hospital and the formation of its medical school. Yet neither these lectures nor those subsequently delivered by Billings at the Lowell Institute were considered worthy of publication by their author, probably because they dealt with material "gone stale," even though viewed from a special angle. But the seed thus sown did bear fruit. At the Johns Hopkins Hospital, Osler and the other professors carried "historical medicine" directly into the clinics, much in the manner which Braatz has adopted and described. And this way of familiarizing the student with the rudiments of the subject might easily be followed by the anatomist, the embryologist, the otologist, the professors of hygiene and medical jurisprudence, and other teachers in the different specialties.

THE FAT CONTENT OF THE BLOOD

Judging by the attention which is being devoted of late to the quantitative aspects of the blood, we may look forward with considerable confidence to a better understanding, in the near future, of the economy of the nutrients in their exchanges between the circulating medium and the body tissues. Some of the constituents of the blood have already been the subject of extensive investigation, notably the sugar and the non-protein nitrogenous substances regarding which we have offered comments from time to time.[1] The sugar-content of the blood is coming to rank with other more familiar quantitative constants like the percentage of hemoglobin or the number of corpuscles, as an index of the existence of pathologic conditions in the metabolism of the body. Urea estimations and other ways of determining such non-protein nitrogen as is furnished by amino-acids in the circulation are being studied in relation to the efficiency of the kidneys as organs of elimination.

Surprisingly little has developed with respect to a different group of blood constituents, the fats, which are quite as common, if not actually as indispensable, as sugar in the nutritional performances of the organism. Lipemia — characterized by an exceptional amount of fat in the blood — is familiar to most physicians as something occurring during fat absorption, when the blood-plasma becomes milky with fat. It is a phenomenon likewise frequently present in severe diabetes.[2] Whereas, however, it is not uncommon to refer to hyperglycemia or hypoglycemia, to uricacidemia, to uremia, etc., somewhat familiarly, attention has only recently been directed to the probable importance of variations in the character and amount of the fatty constituents of the blood. Even the "constants" with respect thereto are scarcely known with any degree of either accuracy or adequacy.

Equipped with a novel method of investigation, based on nephelometry, Dr. W. R. Bloor, recently appointed to the staff of the Harvard Medical School from the laboratories of biological chemistry of Washington University at St. Louis, has approached the problems of the fat-content of the blood under approximately normal conditions.[3] Obviously, we need to understand the variations that may be expected therein before it will be profitable to engage in any elaborate consideration of the perversions that occur or their pathologic meaning. Perhaps the most significant feature of these newest studies is the fact that the fat-content of the blood of dogs is shown to be quite constant both for the individual and the species. The average figure for what may be called the fat-content of the blood under normal conditions, taken at varied times on samples collected twenty-four hours after the last feeding, was 0.6 per cent. The average variation of any animal from the average for all was only 7 per cent.; the greatest variation, 14 per cent. This plainly indicates that there is an efficient regulation. Bloor concludes that this constancy of fat values in the blood of dogs gives sufficient reason to expect a similar constancy in the normal blood-fat value of human beings, and indicates that blood-fat determinations would give valuable diagnostic information in certain conditions.

Feeding fat in the ordinary way caused an increase in the fat-content of the blood beginning in about one hour after feeding and reaching a maximum in about six hours. When the thoracic duct was tied there was no increase in blood-fat after fat-feeding. This does not necessarily prove that no absorption was taking place, but only that if any fat was entering the blood-stream by channels other than the lymphatics, it was being removed as rapidly as it entered.

In connection with recent attempts at the intravenous feeding of fats in the form of the fine emulsion furnished by egg-yolk,[4] it is interesting to learn that the fat in certain types of emulsions may disappear rapidly from the circulation after it is introduced directly into the blood-stream. Why there should be wide variations in their behavior is not yet clear. The point of chief import, we conclude, is the possibility of a rapid removal of even undigested fat to the storage or other depots concerned in fat metabolism.

It has long been understood that the amount of fat in the blood may be somewhat increased in fasting, because the fat is taken up from the fat deposits and carried to the various organs by the blood. The experiment has not always tallied with the theory, however. From Bloor's investigations it is not unreasonable to explain the differences hitherto observed—sometimes a high and again a low blood-fat content in starvation—by the relative availability of the stored fat and especially the fat in the temporary storehouses on the one hand and the rate of utilization on the other. For example, an animal which did not ordinarily show any increase in blood-fat in fasting, was made to exhibit the usual curve of increase of blood-fat in fasting by stuffing with fat-food for a week before the fast. Bloor's results thus plainly indicate that when food is withheld, the increase in blood-fat depends on the nutritional condition of the animal. Narcotics may also have a pronounced effect on the blood-fat content; but that is a topic which demands more study.

RURAL SANITATION

In 1909 the Commission on Country Life reported that "the farm should be the most healthful place in which to live, and there are numberless farmhouses, especially of the farm-owner class, that possess most excellent modern sanitary conveniences. Still it is a fact that there are also numberless other farmhouses, especially of the tenant class, and even numerous rural schoolhouses, that do not have the rudiments of sanitary arrangement. Health conditions in many parts of the open country, therefore, are in urgent need of betterment."

The problem of rural sanitation calls for consideration from two points of view: that of the possible danger of objectionable surroundings and unhygienic practices to the individual on the farm and his immediate neighbors; and that of the menace which insanitary farm conditions may present indirectly to urban communities. The sanitary relation of the farm to the city involves almost entirely the possibility of the spread of actual infection from country to city through milk, meat, vegetables and other farm products. A few years ago it was not uncommon for farmers to meet with a spirit of resistance any suggestion of hygienic improvements which were planned to diminish the danger of the farm as a starting point for the spread of disease. At times there has actually been aggressive opposition to proposed regulations the object of which was defensible from every unbiased point of view. The milk industry could furnish many instances in recent times of actual refusal on the part of farm communities to supply an essential food to the market under conditions that to-day are everywhere accepted as rational and necessary.

A few years ago the apparent indifference of the rural community to the needs of the urban population dependent on the farm for a healthful food supply could be excused on the basis of ignorance. To-day there is no excuse for apathy toward the teachings of modern sanitation. The campaign of education that is being waged throughout the United States by all manner of forces—municipal, state and national—by agencies connected with the Public Health Service, the Department of Agriculture, the experiment stations, the state universities, boards of health, civic organizations and the public press ought to win its way into every rural home that has any ties whatever with civilized communities.

The better understanding of the farmer's unavoidable responsibility toward his distant fellow citizen has in turn reacted to advantage in respect to his own environment. As a recent writer has expressed it: Fortunately with the general advance in rural standards of living in recent years there has come about a considerable awakening of interest among farmers and representatives of rural communities along these lines, as well as among the public as a whole. Modern methods of communication and travel have to a great extent brought the rural districts into closer relationship with the towns and cities. The farmer learns of the improved general health and reduction in the death rate resulting from the decrease of the ravages of contagious disease, which has been brought about through the introduction of such preventive measures as a sanitary water supply, proper methods for the disposal of sewage and garbage, and mosquito and fly extermination, and wishes to avail himself of these benefits.[1]

The country medical practitioner well realizes the futile idealism of much that emanates from an urban desk. Sometimes the most elementary sanitary conditions offer puzzling problems when the expense and feasibility of the proposed remedies are carefully studied. Too often the city reformer forgets the enforced monotony of diet, the lack of recreation and the excessive hours of work which farm conditions may entail in some sections and at certain seasons. There are social as well as economic forces involved in farm life. The reform of rural sanitation, which is undeniably called for in some parts of the United States, must not overlook the personal element so strong in the country dweller. With the exigencies of the situation kept in mind the campaign for improvement in rural sanitation is likely, in the words of a recent writer, to do much to make farm life at once more profitable, more healthful and more attractive, and by so doing contribute to safeguard the food supply, and therefore the health and the efficiency of the nation.

Current Comment

FUNCTIONS OF A CITY HOSPITAL

A pamphlet issued by the Department of Public Welfare of the City of Cleveland deals with the history, functions and possibilities of the Cleveland City Hospital. The following statement indicates that those in charge of this hospital have a clear conception of the invaluable service to the public which can be rendered by a great municipal hospital if properly conducted: "A municipal hospital is an institution of organized society provided by a city to care for the sick. It is but a medical means to a social end, and this end — public welfare — must never be forgotten. The modern hospital has outgrown the narrow field of boarding and treating sick people, and the time has come when a proper city hospital can no longer passively receive the sick from the community at large, without regard for the reason why they became sick, use them chiefly as material and often discharge them without the slightest interest in their convalescence and rehabilitation in wholesome living and working conditions. Hospitals more than any other social agency accumulate the evidence against the dangers to life in the community, dangers from contagion, from ways of living and from industry, and they must feel the responsibility to study this evidence and become leaders in the progress of prophylactic medicine. The idle convalescent is of no more value in a community than the bedridden and scarcely less expensive to support. It is not only charity and social service, but also sound economy for a city to supervise convalescence; to make it such that the patient can return to his work the sooner. A city hospital of to-day must continue to give to a community scientific care for its sick and must afford opportunities both for scientific investigation and for the education of physicians, nurses and orderlies. But above all, it must, through its social service work and through cooperation with all other community social agencies, give a watchfulness over public health and results that will result in more days of life, work and happiness to its citizens."

DO "PATENT MEDICINE" INTERESTS CONTROL THE PRESS?

Most of our readers are familiar with the "Great American Fraud" articles by Samuel Hopkins Adams that appeared in *Collier's* a few years ago. In preparing the matter for the "Great American Fraud," Mr. Adams visited "patent medicine" factories, got in touch with nostrum promoters — and their dupes — and in various ways investigated the subject with the utmost thoroughness. In connection with that series there were one or two articles showing the sinister control that the "patent medicine" interests exercised over the press of the country. The notorious "red clause" in advertising contracts, by which the "patent medicine" makers hoped to enlist the aid of the newspapers as unpaid lobbyists against any proposed health legislation that might interfere with the sale of nostrums — this is history. That the "patent medicine" interests still exercise a baneful control over the press is evident from the facts brought out in a letter from Mr. Adams published in this issue.[1] In his latest novel, "The Clarion," Mr. Adams has put in vivid and gripping form the information he has gained as a newspaper man, and his wide and yet detailed knowledge of quackery and the "patent medicine" business. It is not necessary here to give a synopsis of "The Clarion"; this was done when the book was reviewed recently.[2] It is sufficient to remind our readers that the novel deals with the problems that beset a newspaper that tries to be honest with its patrons. The chief character in "The Clarion" is a "patent medicine" manufacturer, one "Dr. Surtaine," whose nostrum "Certina" brought him wealth and power. Readers familiar with the history of contemporary quackery will recognize in Surtaine a composite picture of several individuals who have amassed wealth through the sale of worthless, fraudulent or dangerous nostrums. If one wished to clothe the intangible, to particularize the general, to materialize the immaterial, he could, as fancy led him, recognize in Mr. Adams' hypothetical nostrum "Certina," such products as "Swamp Root," "Peruna," or a score of others. It is evident from Mr. Adams' letter that the newspapers and book-store proprietors of Binghamton, N. Y., have materialized "Dr. Surtaine's" preparation in the notorious fraud, "Swamp Root." Such might have been expected. But it is a little disheartening to those who were hoping against hope that the newspapers were throwing off the yoke of the "patent medicine" makers, to find that there are still newspapers so recreant to their public trust as to refuse to advertise a novel because it may throw an unpleasant light into the dark places of a local industry.

FURTHER "PATENT MEDICINE" INFLUENCE

In connection with the instance cited above we give another example of the power wielded by the "patent medicine" interests. The story runs that a traveling exhibit sent out by a state board of health contained, among other material, some educational posters on the "patent medicine" evil. One of the placards exposed the fraudulence of a "patent medicine" manufactured and having a large sale in that section of the country through which the exhibit was going. Soon after the traveling exhibit had left the town in which this particular medicine was made, the official in charge of the exhibit received a telegram from a railroad official of another state requesting that the particular exhibit in question be removed from the car because it reflected adversely on a certain one of the railroad's patrons. As the request practically amounted to a demand, the exhibit objected to was removed. This particular incident we may take up in greater detail at some future time; at present it is referred to only to show that the influence wielded by those who have made their millions out of the great American fraud is as real as it is malevolent.

BARE WALLS AND MONOTONY

The bare white walls of the modern sanitary hospital have a certain monotony which, in many instances, forms a dull and dreary aspect to the sick person who must lie for the larger part of every day and find nothing else in his horizon. Brayton[1] refers to a patient who, when he left the hospital, said: "Sister, tell the next patient who occupies this room that there are 391 fleurs-de-lis in the decoration on the wall." Another patient reported to his friends that his room was well aired by two large windows, that there were three fly-specks on the big white walls, and the brass door knob was most interesting. In Indianapolis two units of the City Hospital, known as Burdsal units in honor of the founder, have been decorated so adequately that the foregoing criticism does not apply. Some of the best artists — men and women of national fame — have collaborated in the work. Mr. William Forsythe is general director of the decoration program, and is personally decorating one of the wards for the children. In the children's dining room Mr. Otto Stark has portrayed a "festival of toys." In one of

---

---

[1] Brayton: Indianapolis Med. Jour., 1914, xvii, 497.

the corridors of the children's wards Mr. Carl Graf has illustrated the story of Cinderella. Mr. Weyman Adams, a well-known portrait painter, has included twenty-four portraits of Indianapolis children placed medallion-like in panels between the windows. In the sun parlor the best-known children stories have been depicted in colors by Mr. Clifton Wheeler. In the women's wards work is being done by Mr. T. C. Steele, Mr. J. Otis Adams, Mrs. J. E. Bundy, Mr. William E. Scott and Miss Dorothy Morlin; corridors and panels are being made by Mr. Martinius Anderson and Mr. G. Gaus. A large bronze fountain is being made by Mrs. Myra Richards for the roof garden playground, and a bronze tablet, commemoratory to the donor, by Miss Helene Hibben. A visiting artist, looking over the walls already covered, remarked that there were only two buildings in this country that these decorations recalled, one of them the Boston Public Library, the other, the Congressional Library. The idea, while not wholly unique, has here been carried out with a quality and completeness probably not equaled elsewhere. As Brayton quotes, "These beautiful and peaceful decorations 'may minister to a mind diseased and pluck from memory a rooted sorrow.'" The achievement is worthy of being widely copied if other communities can enlist a similar cooperation of artists.

THE SIGNS OF DEATH FROM FREEZING

It is not clearly understood how severe cold causes death. A variety of causes have been assumed to be at work — accumulation of carbonic acid, paralysis of the vasomotor centers, loss of heat, accumulation of blood in the heart, anemia of the brain, destruction of red corpuscles — all of which tends to show that we really do not know anything definite as to the precise cause. The signs of death caused by exposure to cold are also poorly understood. This is especially unfortunate in view of the fact that in all northern countries cases of death from freezing frequently present themselves for investigation. In Russia, for instance, at least several hundred persons die each year from the immediate effects of severe cold, and in the Medicolegal Institute in Moscow about 2.5 per cent. of all post-mortem examinations concern deaths from freezing. Recently Krjukoff[1] has published the results obtained from a study of the Moscow material with a reference to the signs of death from freezing, and he finds that in 40 per cent. of the cases the presence of swollen and glistening bluish-red or bright scarlet-red spots in the skin of the ears, hands or feet were present and that such spots are reliable signs of the action of cold on the living skin. Cerebral and pulmonary hyperemia and edema were frequently found, and the heart commonly was overfilled with blood: but these appearances were not distinctive. Hemorrhagic erosions were found in the stomach in 72 per cent. Krjukoff regards the absence of glycogen and sugar in the liver as a good sign of death from freezing, particularly valuable because both these substances are present in the liver in acute alcoholism.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ALABAMA

Personal.—Dr. Wesley Earl Drennen, Birmingham, has sailed for Europe.——Dr. George H. Fonde, Mobile, has been appointed a trustee of the Alabama-Bryce Hospital for the Insane, Tuscaloosa.

Fire in Infirmary.—Fire at the infirmary of Drs. Luther L. and Robert S. Hill, Montgomery, November 7, caused serious damage, and necessitated the removal of all patients from the building. This was accomplished without casualty.

Tick Eradication.—Dr. J. A. Kiernan is working on this task for the federal government. Hale, Marengo and Henry counties voted for tick eradication in the last election. Wilcox County is to furnish funds for tick eradication work. Limestone County has entered into a contract with the federal government to assist in tick eradication beginning Feb. 15, 1915. The Alabama Live Stock Sanitary Association has also entered into a tick eradication contract.

Malarial Survey.—Surgeon Rudolph H. von Ezdorf, U. S. P. H. S., has recently been transferred from Mobile to New Orleans and delivered an address at a meeting of the Mobile County Medical Society on "Malarial Survey," in which he outlined the ways in which surveys are made by the public health service in the various cities affected by malarial mosquitoes. A resolution, commending the faithful work of Dr. von Ezdorf during the four years of his stay in Mobile, was adopted by a rising vote.

CALIFORNIA

Want Another Tuberculosis Hospital.—The committee on public health of the San Francisco Medical Society has recommended to the supervisors that the present tuberculosis hospital be used for bed cases only, and the city requires a sanatorium for ambulatory and hopeful cases of tuberculosis.

Personal.—Dr. Frank J. Bailey, Red Bluff, has been elected coroner and public administrator of Tehama County.—Dr. Howard Somers, San Francisco, has returned from Europe.——Dr. Edward E. Dowdle has resigned as resident physician at the Oakland Emergency Hospital and will locate in Hayward.

FLORIDA

State Laboratory Opened.—The State Bacteriological Laboratory at Tallahassee was opened last week.

State Colony for Epileptics.—A campaign for the establishment of a state colony for epileptics in Florida was started in August last, by a series of popular articles which appeared in the Jacksonville *Times Union* in the form of an appeal to the State Board of Charities and Corrections and the charitable and philanthropic people of the state.

ILLINOIS

Life Memberships Conferred.—At the forty-first annual meeting of the North Central Illinois Medical Society held in Wenona, December 1 and 2, certificates of life membership were conferred on Dr. George Allen Dicus, Streator, president of the association; Dr. Thomas H. Trainor, Aurora, and Dr. Thomas W. Burrows, Ottawa.

Personal.—Dr. Enos S. Spindel, Springfield, has been appointed a member of the State Board of Health, vice Dr. James J. Hassett, McLeansboro, deceased.——Dr. Thomas N. Miller, Rockford, who was seriously injured in a runaway accident November 2, is reported to be convalescent.——Dr. Halley A. Smith, Rockford, has started for France where he expects to serve in the army medical corps.

Chicago

Civil Service Examination.—The County Civil Service Commission announces that it will hold an examination the last week in January, 1915, for director of the Psychopathic Institute in connection with the juvenile court. The position carries a salary of $5,000 a year and the examination is to be as to the mental and physical condition of delinquent and dependent children who appear in the juvenile court.

Free Aid to Working Women.—The following women physicians of Chicago have offered to give their services free to working women and also to help in the municipal dance halls. Drs. Sadie B. Adair and Lindsay Wynekoop have been assigned to the south side dance halls; Drs. Blanche Bergman and Agnes Mikkelsen to those on the west side, and Drs. Effie L. Lobdell and Clara P. Seippel to the north side dance halls.

Health Exhibit Opened.—The Chicago Health Department, Board of Education, Municipal Tuberculosis Sanatorium, United States Bureau of Food Inspection, United States Bureau of Animal Industry and Illinois State Board of Health have united their efforts with those of many private organizations of Chicago and elsewhere to produce a new type of expedition picturing health from the standpoint of the common interest. This expedition was opened to the public at the City Club, December 1, and includes all phases of municipal health problems, infant welfare, bad lighting, inadequate school inspection, etc.

LOUISIANA

Tribute to Dr. Dowling.—The New Orleans *State*, in its issue for November 15, says editorially:

> "When the Southern Medical Association elected Doctor Oscar Dowling of Louisiana to its presidency, that body bestowed a merited honor. Dr. Dowling, as president of the State Board of Health, has brought to his work energy, courage, intelligence and enthusiasm. He has set a standard in Louisiana for the discharge of the duties of public office. He has won for the health department of Louisiana a reputation equalled by few and surpassed by none other of the like departments in other commonwealths. The good this has done for Louisiana, in correcting false impressions abroad, in remedying conditions on which some truthful unfavorable impressions were based, has been incalculable. Many thousands of Louisianians will live longer, live more effectively for themselves and for their communities, because of the work Dr. Dowling has done, and the interest he has stirred in cleanliness, sanitation, and decent and right living."

MARYLAND

New Diet Kitchen.—The new diet kitchen which has been presented to the Hebrew Hospital by Mr. Wm. M. Benesch, was formally turned over to the hospital on November 25. The gift was accepted on the part of the institution by Dr. Harry Adler, Baltimore, president of the hospital board. The kitchen is equipped for the preparation of special foods and is also a school for the instruction of nurses in training in the science of dietetics.

Portrait Presented to Faculty.—A life-sized oil painting of Dr. Samuel Clagett Chew, dean of Baltimore physicians, formerly president of the Medical and Chirurgical Faculty of Maryland, a member of the Board of Regents of Maryland for more than forty years, was presented to the faculty November 20, by the Baltimore City Medical Society. The ceremony took place at Osler Hall. The presentation addresses were made by Drs. Charles W. Mitchell and William S. Thayer. Dr. Randolph Winslow, president of the faculty, accepted the portrait on behalf of the faculty.

MASSACHUSETTS

Dental Infirmary Dedicated.—The Forsyth Dental Infirmary for Children, Boston, was formally dedicated November 24. The infirmary is a gift to the city of Boston from John Hamilton and Thomas Alexander Forsyth in memory of their brothers, James Bennett and George Henry Forsyth, and has an endowment of $2,000,000.

Personal.—Dr. John J. Dowling has been appointed superintendent of the Boston City Hospital, vice John C. McCollom.——Dr. H. J. Gosline has been appointed assistant physician at the Danvers State Hospital.——Dr. Charles A. Reese, West Newton, was knocked down by an automobile truck November 22 and painfully injured.

Health Hints to Public.—The annual course of free public health talks given under the auspices of the Robert Dawson Evans Memorial Department of Clinical Research and Preventive Medicine began November 17, at the Memorial Building in Boston, when Dr. Allen J. McLaughlin, the new health commissioner of the state, gave a talk on "The Importance of Public Education in the Prevention of Diseases." The talks will continue to be given each Tuesday evening until May 25, 1915.

MICHIGAN

Tuberculosis Building Opened.—The Anna T. Dodge Children's Building of the Detroit Tuberculosis Sanatorium, was formally opened to the public on Tuberculosis Day, November 29.

Diphtheria General Throughout the State.—Dr. John L. Burkart, Lansing, secretary of the State Board of Health, says that diphtheria is general throughout the state, over fifty cases having been reported from Ithaca alone. Schools have been closed at Bay City and other places.

MINNESOTA

State Cancer Committee.—Dr. William J. Mayo, Rochester, has been appointed chairman of the Minnesota State Committee of the Medical Society for the Control of Cancer. He has associate with him on this committee, Dr. James E. Moore, Minneapolis, and Dr. Warren A. Dennis, St. Paul.

Personal.—Dr. Carl J. Holman, Mankato, has been appointed a member of the State Board of Medical Examiners, succeeding Dr. John W. Andrews, Mankato, who was elected to the state senate at the November election.——Dr. Charles A. Stewart is reported to be ill at his home in Duluth.

Red Cross Christmas Seal Campaign.—The Minnesota Public Health Association, which has charge of the sale of Red Cross Christmas seals in the state, announces a series of prizes to districts and district managers varying from the services of a baby welfare nurse to pennants or banners in consideration of the sale of the Christmas seals.

Bass Lake Preventorium.—The League of Protestant Women of Minneapolis have purchased Oakwood Inn, Bass Lake, for $15,000, and will convert the inn into a sanatorium for the prevention of tuberculosis in children. The institution owns eleven acres of land and is located on the lake shore. Dr. Longstreet Taylor will be in charge of the sanatorium.

MISSISSIPPI

Pellagra Excluded from Natchez Hospital.—The board of trustees of Natchez Charity Hospital, November 11, decided, in view of a reduced appropriation, to exclude all pellagra cases. The Vicksburg Emergency Hospital had previously taken similar action.

State Hospital Overcrowded.—The Mississippi Insane Hospital, Jackson, showed an average of 1,527 for the month of October. The appropriation made by the legislature was based on an average of 1,450 at a per capita of $140 per annum. Thus the institution is caring for 77 patients more than has been provided for by the state.

Free Pasteur Treatment.—By an arrangement perfected by the secretary of the Mississippi Board of Health and the United States Public Health Service, the State Board of Health announces that it will treat all cases of rabies free of charge, provided the persons suffering from the disease are unable to take treatment at the Pasteur institutions located at New Orleans or Memphis. The only stipulation is that the treatment be administered by an official of the State Board of Health.

NEW YORK

County Tuberculosis Hospital.—Suffolk County has voted in favor of a tuberculosis hospital and has appropriated $50,000 for its establishment.

Mental Defectives.—In a recent address Robert W. Hebberd, secretary of the state board of charities, urged an extension of the state institutions for the care of feeble-minded persons. He states that a recent investigation shows that there are nearly 9,000 mentally defective persons in the state outside of New York City who are unsuitably cared for in their homes and in almshouses. A survey of New York City is now being made. A bond issue is recommended as the best means of raising funds to make provision for these unfortunates.

New York City

Roentgenologists Incorporate.—A certificate of incorporation was granted, November 14, to the New York Roentgen Ray Association with the following directors: Drs. I. Seth Hirsch, George Sloan Dixon, Adoniram Judson Quimby, William A. LaField and Archibald P. Evans.

The Common Drinking Cup in Theaters.—An inspection of the theaters of the city has just been completed with reference to the use of the common drinking cup. Of the 429 theaters visited only 16 violations of the law were discovered and 14 of these were in Brooklyn.

Red Cross Seals on Sale.—A large committee composed of citizens of Manhattan has been organized and is conducting a campaign to dispose of 3,000,000 Red Cross Christmas Seals, the proceeds of which go to the Committee on Prevention of Tuberculosis of the Charity Organization Society. Special efforts are being made to bring the importance of this home charity to the attention of the public.

Cancer Research Report.—The report of Dr. Francis Carter Wood, director of the George Crocker Cancer Research Fund, has just been submitted to the College of Physicians and Surgeons of Columbia University. The report reviews the research work of the past year and contains a special warning to physicans against the wide use of colloidal silver salts by doctors in treating various diseases. The results of these investigations are to be published for the benefit of practitioners throughout the country. Dr. Wood states in the report that the laboratory should in time become a central bureau for information on any phase of the cancer question. With this idea in view, a large private collection of slides, amounting to some 3,000 separate specimens, has been turned over to the fund by the director. Several well-known pathologists of Europe have signified their willingness to supply the Crocker fund with a series of specimens illustrating rare forms of tumors.

PENNSYLVANIA

Sanatorium Wing for Children.—The State Health Department has decided to devote the new west wing of the Cresson State Sanatorium entirely to children. The new ward which cost about $300,000 will have small wards, each containing eighteen beds, private rooms, play rooms, etc. The new wing will be ready for occupancy early in the spring.

State's War on Typhoid Reduces Mortality Greatly.—In spite of the recent outbreak of typhoid fever at Lehigh and of the fact that there are a larger number of cases of typhoid in the hospitals of the state at present, there has been a remarkable decline, both in the death-rate and morbidity since 1906, when an active fight against the spread of the disease began in Pennsylvania.

Personal.—Dr. Fred L. Grander, Forest City, fell on an icy sidewalk November 20, fracturing his left shoulder.——Dr. Robert W. Stewart, Pittsburgh, has returned from Europe. ——Dr. Frank V. McConkey, York, has been appointed a medical inspector under the division of Industrial Hygiene of the State Department of Labor and Industry.——Dr. William F. Muhlenberg, Reading, has been elected vice-president of the Pennsylvania-German Society.——Dr. Jesse H. Hazlett, Vanderbilt, is under treatment in the Allegheny Hospital, Cumberland, as the result of a skull fracture received in an automobile accident near Cumberland, November 9.

Philadelphia

Mütter Lecture.—The Mütter Lecture on Surgical Pathology for 1914 was given in the Thompson Hall of the College of Physicians of Philadelphia, December 4, by Dr. Fred H. Albee, New York City, on "The Fundamental Principles Involved in the Use of Bone Grafts in Surgery."

Personal.—Dr. Thomas McCrae has been appointed consulting physician at Girard Hospital.——Dr. Edward K. Tullidge sailed for Europe to serve in the Austrian Field Hospital.——Dr. John B. Carnett has been appointed surgeon at the Philadelphia General Hospital to succeed Dr. Edward Martin, resigned.

Medal to Dr. R. Tait McKenzie.—A silver medal in recognition of his work in athletic sculpture has been sent by King Gustavus of Sweden to Dr. R. Tait McKenzie, physical director at the University of Pennsylvania. The medal bears on one side the likeness of the King and on the other the Royal Arms of Sweden.

Curtin Medical Scholarship.—An effort is being made by the Philadelphia Alumni Society of the Medical School of the University of Pennsylvania to complete the fund for the purpose of endowing a scholarship in the medical school of the university in the name of the first president of the society, Dr. Roland G. Curtin. Subscriptions to the fund should be sent to Dr. L. H. Adler, Jr., 1610 Arch Street, Philadelphia.

News of Medical Institutions.—The campaign fund for the hospital to be known as the Providence General Hospital, Germantown, has reached over $29,000. Fifty thousand dollars is necessary to start the building of the first wing on the 7-acre property at Wissahickon Avenue and Lincoln Drive. ——about $1,300 was contributed November 18, "Donation Day" at the Children's Hospital, which receives no money from the city or state.

CANADA

Montreal Hospitals Seek Financial Aid.—The General, Western and Notre Dame hospitals of Montreal have appealed to the board of control of that city for funds to carry on their work. It was pointed out that the hospitals would have to meet a combined deficit at the end of the present year of $84,000.

University Professor Dies.—G. R. Mines, M.A., professor of physiology at McGill University, Montreal, died in his laboratory, November 7. Professor Mines had been experimenting on himself regarding the phenomena of the heart action and respiration and it is believed, lost his life while engaging in experimentation of this nature.

Decrease of Drinking in Canada.—Canada produced in the fiscal year of 1914, 6,972,583 proof gallons of spirits as compared with 6,458,452 in the previous fiscal year. The per capita consumption of spirits was 1.061 gallons as against 1.112 in the previous year. The average consumption has, however, been going up in Canada since 1886 when it was only .711 per capita. Canadians are drinking more beer, the consumption per capita being now placed at 7.200 as compared with an average of 3.840 in the last four decades. There has been little decrease in the average consumption of wines which is now .124 as compared with the previous average of .119. The consumption of tobacco per head is now 3.711, a little less than the previous figure of 3.818.

Medical Reciprocity with Great Britain.—The action of the home authorities in refusing commissions to Ontario graduates to serve in either the British army or navy unless they are able to comply with the regulations of the General Medical Council has again precipitated the whole question of medical reciprocity between the provinces of Canada and the home land. The Dominion Medical Council has, as yet, not established any measure of medical reciprocity; the eastern provinces have Quebec, New Brunswick, Nova Scotia and Prince Edward Island. It is stated that the executive of the Ontario Medical Council has refused to call a special meeting of council looking toward immediate reciprocity with Great Britain, on old grounds which are well known.

Progress Made in the Tuberculosis Campaign.—Since March, 1913, nine additional institutions for the tuberculous have been opened in different parts of Canada—one at Ottawa; Brantford; Mount Sinai at Ste. Agathe, Quebec; Windsor; River Glade, N. B.; Halifax; The Preventorium, Toronto; Queen Mary Hospital for Tuberculous Children, Weston, Ont.; The Connaught Home for Nurses at the same place; the Preventorium at London, Ont. Extensive additions have also been made to the Provincial Sanatorium at Kentville, N. S.; the Freeport is about ready in Waterloo County, Ont.; the Provincial Sanatorium at Qu'Appelle, Sask., is being erected. Prince Edward Island and Alberta are also making moves in the same direction. Calgary has voted $30,000 for a municipal hospital for advanced cases, and Quebec City has also raised over $60,000 for the same purpose. In twelve sanatoria reporting on the cost of maintainance, the average cost of each patient per day is $1.55.

GENERAL

Health Officer Appointed.—Lieutenant Douglas W. McEnery, M. C., U. S. A., has been appointed special health officer of the city of Panama.

Error in Article by Dr. DeBuys.—In the article by Dr. L. R. DeBuys, entitled "Amebic Dysentery in Children," printed in The Journal for November 21, p. 1806, in table 2, column headed "Ameba," the dates February 12 to 16, there should be a plus sign indicating that ameba were found on these dates.

Duluth and Superior Physicians Meet.—At the annual meeting, November 18, of the Interurban Academy of Medicine, whose membership includes physicians of Duluth, Minn., and Superior, Wis., Dr. Henry A. Russell, Superior, was elected vice-president; Dr. Archibald L. McDonald, Duluth, secretary-treasurer.

Experimental Biologists to Meet.—The federated meeting of the Southern Experimental Biologists comprised of The American Physiological Society, American Society of Biological Chemists, American Society of Pharmacal and Experimental Therapeutics and the American Society of Experimental Pathology will hold its next meeting at the Washington University Medical School, St. Louis, December 28-30.

Virginia University Alumni Organized.—At the meeting of the Southern Medical Association, the University of Virginia Medical Alumni organized with the object of advancing the interests of the University of Virginia Medical School. The following officers were elected: president, Dr. Hugh H. Young, Baltimore; vice-president, Dr. John Staige Davis, University, Va.; secretary, Dr. Seale Harris, Mobile, Ala., and treasurer, Dr. Thomas V. Williamson, Norfolk, Va.

Meeting of Tri-State Physicians.—At the thirty-first annual meeting of the Tri-State Medical Association of Tennessee, Arkansas and Mississippi, held in Memphis, November 17 to 19, the following officers were elected: president, Dr. William P. Hicks, Earle, Ark.; vice-presidents, Drs. Jacob L. Hare, Wynne, Ark.; B. Vernon Dickson, Covington, Tenn., and Ephraim R. McLean, Cleveland, Miss.; secretary, Dr. James L. Andrews, Memphis (reelected); treasurer, Dr. James A. Vaughan, Memphis (reelected).

Federal Foot-and-Mouth Quarantine Partially Lifted.—An order, to become effective November 30, has been issued, releasing from some restrictions of live stock quarantine certain counties in Wisconsin, Illinois and Iowa. Cattle from these counties may be shipped in interstate commerce for immediate slaughter and for feeding purposes, but may not be shipped out for feeding elsewhere. This release order is the first issued since the quarantine was ordered, and will be followed as soon as possible by similar orders lifting the quarantine in other localities. Confidence is felt that the epidemic is now under control and will soon be eradicated.

Medical Missionaries Meet.—In spite of the confusion in mission fields as a result of the war in Europe, the Sixth Inter-Denominational Medical Missionary Conference held in Battle Creek, Mich., November 17-20, was attended by 200 workers from home and foreign fields. The probable effect of the war on mission work was very generally discussed, the consensus of opinion being that a temporary withholding of mission gifts would be experienced, but that the final effect would be a broader brotherhood and a most salutary condition in mission work in general. The conference will meet again in 1915 in Battle Creek.

Bequests and Donations.—The following bequests and donations have recently been announced:

Howard Hospital, Philadelphia, $5,000 to maintain a free bed to be known as the Annie E. Ulmer bed; West Philadelphia Hospital for Women, a bequest of $1,000 by the will of the late Annie Mathews.

Bieur Cholim Hospital, Jerusalem, and Anniston Hospital, Anniston, Ala., each one-fourth and the National Jewish Hospital for Consumptives, Denver, one-half of the estate of L. H. Caplan, Anniston.

Charity Hospital, New Orleans. La., $1,250 by the will of Mrs. Ida P. Richardson, New Orleans.

Church of St. Luke and Epiphany, Philadelphia, a donation of $1,000 to start a fresh air fund; University of Pennsylvania, Philadelphia, about $1,000,000, to be divided among the library, hospital, for the maintenance of free beds, for the system of hydropathic treatment, the department of cutaneous medicine in the Medical School for the advancement of its work and the department of archeology and paleontology, by the will of Dr. Louis A. Duhring.

Maimonides Hospital, Chicago, an appropriation of $2,000 by the Federated Orthodox Charities of Chicago.

Harvard Medical School, $25,000, the income to be used for cancer investigation work; Massachusetts General Hospital, $25,000 for the endowment of a free bed by the will of Mrs. Endicott, Boston.

FOREIGN

Professor Erb's Fiftieth Professional Anniversary.—In October the well-known Heidelberg neurologist, Prof. Wilhelm Erb, completed the fiftieth year of his professional career. His son was one of the first to fall on the firing line, as already mentioned in these columns.

Death of Emmerich.—The death is reported of R. Emmerich, professor of hygiene at the University of Munich, author of numerous works on hygiene and epidemics, aged 62. His views on the importance of the nitrates in the soil as a factor in cholera were reviewed in The Journal, 1904, xliii, 640.

Decorations for Members of the Profession.—The grand cross of the Order of Alfonso XII has recently been presented to the professor of pharmacy at the University of Madrid, J. R. Carracido, who is also a senator, and the Isabella cross to S. Recasens, professor of gynecology at the same seat of learning. The decorations were conferred, the announcement reads, for distinguished services to the *cultura nacional.*

Death of Leading Italian Hygienist.—Our latest exchanges bring obituaries of Angelo Celli, aged 57, to whom Italy owes its present partial emancipation from malaria. He has long been professor of hygiene at the University of Rome, chief of the national board of health and senator of the realm, and to his initiative is due the government monopoly of quinin and its sale practically at cost in every post-office. He was also influential in legislation on the working hours for women and children, in the reclaiming of the marshes around Rome, and other public welfare works. In collaboration with Marchiafava, he published the first description of the meningococcus, and of certain phases of the malaria parasite, and was a frequent contributor to the literature on various topics of internal medicine. He was one of the leading scientists of the world invited to speak at the International Congress of Arts and Science held at the World's Fair in St. Louis in 1904.

WAR NOTES

American Hospital Opens in Petrograd.—An American hospital with a capacity of forty beds, the gift of the American colony in the city, was opened at Petrograd November 28.

More Red Cross Surgeons for Russia.—The American National Red Cross are sending two additional surgeons to reenforce the American Red Cross Hospital units already sent.

The Red Cross in Servia.—Dr. Edward W. Ryan, director of a hospital unit sent to Servia, states that surgeons are very scarce in that country and with about 50,000 wounded, the work is exceedingly heavy. The nurses are working from 8 o'clock in the morning until 7:30 at night.

Precautions Against Disease.—Folkestone is now practically the only port in England open to commercial and passenger business from the Continent, and the health officers at that port are taking unusual precautions to prevent the admission of disease into England from the war zone.

Work of the Japanese Red Cross.—The Japanese Red Cross has sent detachments of surgeons and nurses to Russia, France and England, and quantities of hospital supplies for Belgium and Servia. They have also equipped two hospital ships which are caring for the sick and wounded of Germany and Japan.

Needs of American Hospital.—Dr. James A. Blake, in charge of the American Ambulance Hospital, Paris, has cabled to Mrs. George Wharton Pepper, Philadelphia, that the following supplies are needed for the work of the hospital: surgical gauze, ice bags, hot-water bags, rubber gloves, bed pans, rubber sheeting, syringes, rubber tubing, underclothes, pajamas, abdominal belts, socks, mufflers, scarfs, etc.

Red Cross Units for Servia.—Two Servian Red Cross units, Nos. 2 and 3, sailed for Patras, Greece, on the *Finland,* November 21. The physicians in unit No. 2 are Dr. Ethan Flagg Butler, Rochester, Minn., director; Dr. S. H. Rodger, Knoxville, Tenn., and Dr. James F. Donnelly, New York City. The medical director of the Red Cross unit No. 3 is Dr. Ernest P. Magruder, Washington, D. C., who is assisted by Drs. Clapham P. King, Annapolis, Md., and Morton P. Lane, New Orleans.——Dr. Dean F. Winn, Atlanta, Ga., sailed on the same steamer to join the Russian Red Cross unit.

Proposed Exchange of Medical Prisoners.—The *Münchener med. Wochenschrift,* October 27, states that the organized physicians of Germany (Verband der Aerzte Deutschlands) have petitioned the Prussian state department and war department to request the ambassador from the United States to propose to the government of Great Britain that the physicians who have been taken prisoners by the contending armies should be allowed to return home. They ask that this should be done whether the medical prisoners are or are not of the age subject to military conscription. Our exchange comments that time alone will tell whether this attempt will be successful or not.

Medical Supplies to German Red Cross.—On board the steamer *Potsdam* which sailed from New York City, November 10, the following supplies were sent to the German Red Cross: ten cases of hospital clothing, 2,000 pounds of bandages, 100 bales of absorbent cotton and 6,000 yards of gauze; and for the American Hospital in Munich 1,000 pounds of bandages, 50 bales of absorbent cotton and 4,000 yards of gauze and ten cases of hospital clothing.——The *Rochambeau,* which sailed from New York, November 14, carried the following hospital supplies for the French Red Cross: 20,000 pounds of absorbent cotton, 20,000 bandages, 10,000 yards of gauze, 10,000 yards of starched gauze for splints, 10 gallons of iodin, 2 barrels of alcohol, 500 blankets and 20 boxes of hospital clothing.

Compulsory Insurance in Germany and Austria.—The war is playing havoc with the organized state insurance of workingmen against sickness and accident. As the insured breadwinners have been drawn into the army, they have stopped paying their regular monthly premiums, and the *Kassenkranken* find that their business is practically all outgo with little coming in. Each has been collecting for years a reserve fund, but if this should become exhausted, the insurance companies would have to suspend operations. They have cautioned the physicians in their service to be extremely economical with dressings, drugs, etc. At some points they have stopped sending the tuberculous insured for the regulation course of sanatorium treatment, and the medical profession is alarmed at the danger of the spread of tuberculosis in the homes when nothing comparatively is being done for bacilli-scattering tuberculous working people.

American Red Cross Units Located.—Unit G of the American Red Cross has been located at Kosel in Southeast Germany, near the borders of Russia and Austria. It is attached to a military hospital of about 800 beds and has about 700 patients in its care. Dr. Bial F. Bradbury, Norway, Maine, is in charge of this unit.——Unit I is in charge of Dr. Charles H. Sanders, Washington, D. C., and is located in Gleitwitz, about 30 miles from Kosel, in a theater that has been converted into a hospital with accommodations for about seventy patients.——The units sent to Russia are said to be stationed at Kiev, back of the line of the Russian army in Austria, Galicia.——Unit D has left the Haslar Royal Naval Hospital, Gosport, and has joined Unit F at the American Woman's War Hospital, Paington.——Unit K, in charge of Dr. Cary Snoddy, is located at Vienna, Austria.——The unit located near Pau, France, of which Dr. Reynold F. Kirby-Smith, Sewanee, Tenn., is medical director, writes that medical supplies are urgently needed there and that the unit is located in the Palais d' Hiver, which has been converted into a hospital.——Unit E, located at Budapest, of which Dr. Charles E. McDonald, Salem, N. J., is medical director, has been given a modern building with 200 beds and properly equipped for a hospital.

German Medical Officers at the Front.—The *Berliner klinische Wochenschrift* publishes a reply from Körte to some criticisms of the work of the medical officers in the field, in which he says that gangrene is liable to develop in a serious wound of the leg even under the most scientifically applied dressings. To say that the dressing caused the gangrene is a far-fetched claim. In the district in his charge, he says, he has been amazed at what the medical officers are able to accomplish. In every field hospital and medical corps he has found at least one and generally several trained surgeons. "The task of applying the dressings and getting the men to bed (lying on straw), with scant assistance, is a hard one even when there are only a few hundred wounded. But when the wounded number thousands, the task is beyond human powers to accomplish it all. Whatever is humanly possible is done. It is easy for those at home to criticize, but it would be hard to do any better. Our work is not light, and it takes nerves of iron. In regard to the Belgian physicians, I have heard only praise, and I have seen much of their work. Our German wounded do not require aid of Belgian surgeons now, as they are all cared for in German field hospitals; there are five now in and around Brussels. The leaders among the Belgian surgeons, Depage, for instance, are faultless." [It will be remembered that Professor Depage here referred to presided at the Fourth Congress of the International Society of Surgery held at New York last spring. It is especially appropriate, considering what has followed since last April, to quote the first few lines of his opening address: "The first three meetings of the International Surgical Society took place in Belgium. We gave the preference to a neutral country so as to clearly define the scientific and at the same time the fraternal character of our association. It is not necessary for me to tell you that it is the privilege of our little Belgium to offer a meeting place to the learned men of all nationalities, covered by Europe herself with the shield of peace and liberty."]

LONDON LETTER

London, Nov. 18, 1914.

The War

There are being trained in this country 1,250,000 men for the new army, and recruits continue to be enlisted in large numbers every day. For a few days a lull occurred in the large number joining, but the outcry of the authorities that more men were still wanted at once restored matters. A movement is also on foot for the formation of defense forces from civilians who cannot join the army, but desire to defend their homes in the improbable event of an invasion. The government has been asked to say what should be done so that those willing to take up arms may ensure the rights of combatants for themselves. They have replied that the matter is under consideration. No doubt they are for the time too busy with the more pressing problem of the new army to attend to a new organization. Every means is being taken to safeguard the health of the recruits, mostly very young men. The public is appealed to not to show their friendliness for the soldiers in the usual manner of giving them intoxicating drinks, and the saloons are compelled to close at 10 p. m. instead of the usual hour, 12. Arrangements are being made for lectures to the recruits on the dangers of venereal disease.

The Health of the Troops in the Field

All the reports seem to show that the health of the troops in the field is excellent and that disease has not yet become a factor in invalidity to any extent. Typhoid fever has been mentioned in German reports and cholera in Austrian, but we appear to have had no experience with either disease. The illnesses most frequently mentioned in our reports are pneumonia and rheumatism—natural results of the prolonged exposure to cold and wet in the trenches. Cases of dysentery have occurred, but not in any numbers. Possibly no army in the field has ever before had its wants so well supplied as ours. Our lines of communication, including the sea, have never been even threatened, so that ample supplies of all kinds have been insured. At the front they are conveyed to the troops by a well-organized system of motor transport. The soldiers are so well fed that they have often been able to give from their abundance to the destitute French and Belgians flying from the invaders. With the approach of winter our women are preparing large quantities of woolen garments to send to the soldiers. The queen, who has organized this movement, has made an appeal for 300,000 body belts and pairs of socks, which has met a ready response. The Indian soldiers have not been forgotten, and a special fund is being organized for their benefit.

Consultants to the Royal Navy

The appointment of consulting physicians and surgeons to the army at the front has already been announced. The following well-known consultants have been appointed to the navy: Sir W. Watson Cheyne, Mr. G. R. Turner, Mr. Arthur Edmunds and Mr. C. H. M. Hughes (Naval Hospital, Chatham); M. G. Lenthal Cheatle, Dr. H. D. Rolleston and Mr. C. W. Morris (Naval Hospital, Haslar); Mr. Raymond Johnson (Naval Hospital, Plymouth); Sir Alfred Fripp and Dr. D. A. Shields (H. M. Hospital Ship *Sheelah*), and Sir William Macewen.

The British Red Cross

This society has now organized in Great Britain 359 hospitals containing 11,730 beds, as well as despatched surgeons, nurses and material of all kinds for the sick and wounded to France. It has also acquired a steam yacht of 380 tons for a hospital ship which will have twenty-one beds for private soldiers and three separate cabins for officers.

Appeal from the French Red Cross

An appeal for motor cars and funds for their upkeep has been made on behalf of the French Red Cross and has received the influential support of the queen and others. It is pointed out that the front held by the French troops is at least six times as long as that held by our own. With less population than ours the French have nearly ten times more soldiers in the field. Since nearly the whole of the active male population of France is under military orders, there is hardly any one left to whom the French authorities can appeal for more voluntary assistance, now that the supply of French motor cars has been used up. Belgium and France have supplied the battle ground for a war which has not yet inflicted any of the horrors of invasion on England, and the districts devastated by Germany are precisely those which, in coal fields and in beet sugar, are among the wealthiest in France, so that the damage done already is equivalent to the war indemnity paid by France in 1871. When cars are lent the owners can themselves drive and bring their own mechanic, can themselves drive and be provided with a mechanic, or can send their cars alone. The French Red Cross will arrange the cars in units of six, so that a group of half a dozen friends can work together if they wish. A central depot in London is being arranged for the committee, where all cars offered will be inspected.

The Wounded at Home

Though the wounded are distributed in the hospitals throughout the length and breadth of the land, and hospitals have been improvised everywhere for their reception, so great is the number now that difficulty is beginning to be felt in the accommodation of ordinary hospital cases. A Dublin surgeon, Sir Thomas Myles, points out that the recent arrivals of wounded soldiers from France have taxed the general hospitals to their full capacity. He suggests the immediate erection of a temporary hospital capable of holding a thousand beds. Last week 700 wounded were landed in Dublin. The cases are more serious than those received earlier. Most of the patients are suffering from septic wounds, more or less serious, but comparatively few show any signs of general sepsis. The infection generally appears to be of *Staphylococcus aureus*, though a certain number of wounds have *Bacillus pyocyaneus* present.

Effect of the War on the Medical Schools

As stated previously, the war has had the effect of greatly diminishing the number of students in the medical schools, because some have gone to the front as dressers and others have joined the fighting ranks. Against this, there has been a gain in another direction. Medical students among the Belgian refugees; and Russian and Japanese students who were studying in the German schools, but had to leave in consequence of the war, have been admitted. This novel experience has caused a difficulty in that one group of students has to be addressed in French, while Russians can be spoken to only in the German language. Cambridge University is giving hospitality to the expatriated. Unofficial courses are being given there to refugee students by eleven Belgian professors from Louvain. Facilities are also given for students who understand English for attendance at the ordinary courses. Assistance is being given to those unable to meet the moderate charges of four or five dollars a week for board and lodging, but to be eligible for such assistance and for free courses the students must submit themselves to a medical examination before the Belgian authorities, now in this country, and obtain a certificate of unfitness for military service. (The medical schools of Belgium were described p. 1751.)

The Treatment of German Prisoners

An official from the American embassy, by request of the German government, has visited the German prisoners in this country and made a report. He gives the daily rations already stated in The Journal, and adds that an ample supply of utensils for cooking is provided. The prisoners manage their own cooking. Each man has delivered to him a plate, knife, fork, spoon and mug. Each camp has a canteen at which fruit marmalade, sweets, biscuits, preserved meats, tobacco, etc., can be bought at moderate prices. The scale of prices is settled by the commandant. The regulation directs that each man is to receive two warm army blankets. The regulation is being carried out, but there has been some delay in the issue of the second blanket in certain cases. The issue of the second blanket to every prisoner will be completed as soon as possible, and before the coming of cold weather. In the roofed-in camps most occupants have wooden bedsteads, made by themselves from wood handed over to them for the purpose. The official heard the complaint made that not every prisoner had yet got a bedstead, as the wood provided had not quite sufficed to go round. He was told that the wood had been ordered and that the deficiency would soon be made up. Along with the wooden bedsteads, straw mattresses have been provided. In the open-air camps each tent has twelve inmates who sleep on the wooden floor of the tents on sack beds. Most of the prisoners made no complaint about the sleeping arrangements. Some few, who came from the better classes, missed their own soft beds to which they were accustomed. But they are allowed to buy what provision they please with their own money, and in most cases plenty of money is forthcoming. An outfit of good cut from warm practical cloth material, with underwear, shirts, socks, shoes, all of excellent make, pocket handkerchiefs, brush and comb has been given to all men needing them. Sufficient facilities are given for washing all clothing, and a copious supply of shower baths is forthcoming. In the roofed-in camps warm water baths are provided. Soap is supplied in unlimited quantity for cleaning purposes.

Death of Captain Angus Macnab

The death of Captain Angus Macnab, the ophthalmic surgeon to King Edward VII Hospital at Windsor, whose studies were pursued at Edinburgh, Moorfields, Freiburg and Vienna, the translator of Axenfeld's Bacteriology of the Eye and of Lolunaun's *Disturbances of the Visual Functions*, has given rise to deep regret, especially among the London Scottish Regiment, whose medical officer he was. Captain Macnab was with his regiment in the trenches rendering aid to the wounded, when, in a charge, he was fatally wounded.

Army Medical Casualties in the War

Since my last report the casualties among medical officers of the army have been: killed, 3; died of wounds, 3; wounded, 11; missing, 5; prisoners of war, 6. Captain H. S. Ranken, who died of his wounds on September 25, was awarded the most coveted distinction, the Victoria Cross, for valor, "for continuing to attend to wounded after his thigh and leg had been shattered" on September 20.

PARIS LETTER

Paris, Nov. 12, 1914.

Hughes' Electromagnetic Balance and Its Application to Military Surgery

The celebrated electrician, Hughes, once devised a little electromagnetic apparatus by which it is possible to discover the location of a metallic mass such as a piece of money or a bullet. This old invention seems to have been entirely forgotten until M. G. Lippmann, professor at the Faculté des sciences de Paris recently brought it to light at the Académie des sciences in the hope that it might be profitably employed in military surgery. It is simple, light, portable, inexpensive and easy to construct. It might be used in the numerous cases in which roentgenography is not available. It is composed of an electric battery, an interrupter and two little induction coils (Ruhmkorff without soft iron) of which the primaries are in the battery circuit and the secondaries are in series with a telephone, the receiver of which is held to the ear of the observer. The apparatus is so constructed that the opposing electromotor forces which act on the telephone are exactly equal, and, while they are in equilibrium, the telephone remains silent. If one of the coils is brought near a metallic mass, a sound is heard over the telephone. This is because induced currents arise in the metallic mass and react on the nearest coil but not on the other thus disturbing the electric balance. The sound of the telephone thus reveals the approach of the metallic mass. If the latter is magnetic (fragment of shell or German balls) the effect will be still more marked, since the magnetic mass reinforces the induced current in the nearest coil. The electromagnetic balance is therefore more sensitive to the approach of a German ball than of a French ball.

The Treatment of Tetanus by Large Doses of Chloral

November 4, Dr. Dammler, chief physician of the army, read a paper on this subject before the Académie de médecine. In 1889 he had occasion to treat a case of tetanus with chloral in doses of from 20 to 25 gm. per day. This procedure was then recommended by Professor Verneuil. At present Dammler administers a dose of 6 gm. of chloral every six hours until the patient is in such a state of torpor that all hyperexcitability from the tetanus is abolished. Professor Capitan recently employed Dammler's method with complete success in a particularly serious case of tetanus.

Services Rendered by Sanitary Dogs in the Present War

In previous letters I mentioned the attempts which have been made to train sanitary dogs and to supply our army with a sufficient number of dogs especially trained to search for the wounded (The Journal, Aug. 26, 1911, p. 751; Jan. 25, 1913, p. 299). From the beginning of the mobilization, the Institut de psychologie zoologique requested of the ambulance attendants to whom the sanitary dogs were entrusted brief reports on the conduct of their aids under fire. M. P. Hachet-Souplet, director of the institute, has just published some of the numerous letters which he has received on the subject. They are, in the main, very encouraging. No doubt it would be possible to criticize some details of the instructions given to the dog. Thus, the plan of having the dog bring back the wounded man's cap or handkerchief seems bad. Still the sanitary dogs are rendering important services and it is regrettable that there are not several for each ambulance.

An Association française pour le dressage du chien de guerre has just been formed. Already a large number of dogs have been given to it and sporting societies have opened their immense grounds for its use.

Belgian Physicians on French Ships

The minister of the interior has just authorized the employment of Belgian physicians on French merchant vessels during the war.

The Resumption of Courses in the Paris Medical School

The Faculté de médecine de Paris has just resumed its courses but its program is markedly abbreviated. All the courses for first- and second-year students are to be given under ordinary conditions. All the other courses are postponed until the summer semester. Courses in internal and external pathology, however, are to be given during the winter semester. The clinics remain open to the students.

Personal

November 10, the Académie de médecine elected as national associate Dr. Langlet, professor and director of the Ecole de médecine de Reims and mayor of that city.

Women-Doctors' Hospital at the Front

The hospital organized and controlled entirely by English women doctors at Paris has vindicated its efficiency. It has been placed officially under the War Office, and is permitted to draw rations and fuel from the army stores. One of the women orderlies has been appointed quartermaster. A receiving hospital has been established in Boulogne, whither half of the staff has gone, and is now working under military control. Although the hospital is only a freight shed at the railway station, an excellent operating theater has been fitted up, and the fair surgeons have been earning great commendation from the military medical inspectors.

BERLIN LETTER

Berlin, Oct. 28, 1914.

The War

Considering the great distance at which the present firearms, not only of the artillery but even of the infantry are fired, it is inevitable that dressing stations should be placed too near to the firing line and that they will be reached by missiles. Moreover in view of the great distances at which the opposing troops so often stand, it is inevitable that the Red Cross will not always be recognized. In addition, there are the injuries by bombs from the airships. All these circumstances have as a result that we already have lost a disproportionately large number of surgeons. While, in Franco-Prussian War, 1870-71, of 4,062 physicians on the field of battle on the German side, only nine fell and two later succumbed to their wounds, nearly 100 of about 9,000 surgeons, at present in the field, have fallen and thirty-seven have been wounded besides thirteen missing and three taken prisoners. Presumably among the missing are some who have fallen and hitherto have not been found but the greater number must have been taken prisoners.

The murderous battles have naturally had a large number of deaths and wounds among the soldiers. With regard to the extent of the losses, definite figures, naturally, cannot be given. As the reports from many parts of the army are received under very difficult conditions with great delay, the hundred lists of losses so far published give already a very sad report. Fortunately, so far the experience which has been procured in late wars with modern weapons, has been repeated with our wounded as, according to our observations, the wounds heal with surprising quickness and with proportionately small functional disturbance. Lamentable also are the large numbers of tetanus cases in our army. Relatively little disease has been reported and especially it is to be noted, that epidemics have not been hitherto observed. To be sure, in the east and in the west there have been a few hundred cases of typhoid and dysentery but these are quite sporadic and not in the nature of an epidemic, so that we may hope that this morbidity figure will be limited.

The German Red Cross

An editorial in the issue for October 29 of the *Deutsche medizinische Wochenschrift* compares the donations to the German Red Cross during the present war with those received during the Franco-Prussian War in 1870-71. At that time France was the only foe, and all the other nations contributed lavishly to the German Red Cross, a total, in round figures, of $1,875,000 cash and $3,875,000 in goods. Austria contributed $25,000; Belgium, $28,250; Denmark, $7,000; Greece, $5,750; Germans in France, $7,250; England, $140,000; Italy, $17,500; the Netherlands, $10,250; Portugal, $5,250; Russia, $100,000; Sweden and Norway, $6,750; Switzerland, $27,750; Spain, $2,750; Turkey and Roumania, $9,000; United States, $833,333 (3⅓ million marks); Central America, $47,500; South America, $187,500; Asiatic Turkey, $1,750; India, $50,000; China, $12,500; Japan, $17,500, and the Philippines, $3,500. Egypt donated $10,000; southern and western Africa, $13,750, and Australia, $30,500. The donations in hospital supplies, products of the various countries and jewels and art wares donated, besides the above cash, are placed at an estimated value of $3,875,000 (15½ million marks). The German Red Cross raffled off jewelry, etc., donated and thus added to the cash donations. The editorial compares the conditions in 1870-71, when all the other state were neutral, with conditions now "with half or three-quarters of the world as our foe and the rest keeping a neutral attitude, at the best wishing us well, but mostly a laboriously maintained neutrality (höchstens wohlwollend, meistens mühsam erzwungenen Neutralität uns gegenüber)." Consequently, it continues, the German Red Cross must rely on its own land almost exclusively for contributions in this campaign. To date, in addition to the American Red Cross expeditions, only Greece and Luxemburg have sent or signified their intention to send contributions or expeditions. The American contingent consisted of twelve physicians, fifty-six nurses and seven carloads of supplies, and half of these were destined for the scene of the war in Austria. In Germany, to date, August 1 to October 29, $1,250,000 have been contributed to the Red Cross.

The editorial comments further that donations in Germany are being distributed more now than formerly, other funds receiving contributions as well as the Red Cross, such as the fund for the care of widows and orphans and local organized relief work, and private benefactions. "This decentralization," it adds, "has both a good and a bad side. The essential point is only that our brave soldiers—and their families—shall be protected against lack of care and clothing. That they have had to suffer much in this respect which might have been avoided by the organization—notwithstanding all the military difficulties and exigencies—seems to be beyond question. Even the best efforts of the Red Cross were unable to provide better facilities for conveying the wounded at times. Of late, however, conditions in this respect have been materially improved."

Decoration with Pension Attached for Bavarian Medical Officers

The war department of Bavaria has announced the foundation of a new order, the Order of the Medical Corps (*Militär-Sanitätsorden*), which will take the place of the decoration founded in 1812, the *Militärsanitäts-Ehrenzeichen*. The new order will be conferred for distinguished services during war time by Bavarian physicians or physicians from outside of Bavaria who render special services to the members of the Bavarian army. The decoration is of two classes, and the one of the first class is contingent on having already received the other. The order carries with it a life annuity of $75 or $150 (300 or 600 marks).

Marriages

A. Marion Wassam, M.D., Galveston, Tex., to Mrs. Mary Hambly of Washington, D. C., at Beaumont, Tex., November 5.

Hiram Watkins Kostmayer, M.D., to Miss Carrol Houston Reichel, both of New Orleans, at Chicago, August 31.

Robert Bruce Wallace, M.D., Lecompte, La., to Miss Emma Dorothy James of New Orleans, November 9.

William P. Lee, M.D., Northfield, Minn., to Miss Alice Katherine Wentworth of Winthrop, Me., November 7.

Leonard Waterman, M.D., Norman, Neb., to Miss Elizabeth Luelle James of Calumet, Mich., September 16.

Emil J. Goldring, M.D., Philadelphia, to Miss Della Meitner of Roxborough, Philadelphia, November 3.

Walter Franklin Bleifuss, M.D., Elgin, Minn., to Miss. Lydia N. Lubahn of Racine, Minn., recently.

Edward A. Marrs, M.D., Moline, Kan., to Miss Blossom N. Thompson of Howard, Kan., September 27.

Lucious W. Brock, M.D., to Miss Dan Tate, both of Mount Herman, La., at Amite, La., November 10.

William R. Shaefer, M.D., Columbia, Mo., to Miss Alice Dixon of Kansas City, Mo., November 10.

Horace F. Pierce, M.D., San Francisco, to Miss Christine Buist of Moorestown, N. J., November 11.

William H. Harris, M.D., to Miss Marie Mercedes Friedrichs, both of New Orleans, October 26.

P. A. Surg. Willard J. Riddick, U. S. N., to Miss Adrienne Ziegler of New Orleans, October 28.

Percy G. Drake, M.D., Manila, P. I., to Miss Reta Helen Taylor of Baltimore, October 22.

Paul A. Ramsel, M.D., Shiner, Tex., to Mrs. Ida Kunneth of Rockdale, Tex., November 10.

Jesse Wright Downey, Jr., M.D., to Miss May Lee Willis, both of Baltimore, November 7.

Charles Jacob Barker, M.D., to Miss Aline Coulon, both of Thibodaux, La., October 14.

D. G. Mahood, M.D., Orchard, Neb., to Miss Nora Morley of Onawa, Iowa, October 28.

Porter D. Blackburn, M.D., Houston, Tex., to Miss Alice Dodd of St. Louis, November 10.

Lovell Langstroth, M.D., to Miss Dora Winn, both of San Francisco, October 23.

Deaths

Theodore Willis Fisher, M.D. Harvard Medical School, Boston, 1861; surgeon of the Forty-Fourth Massachusetts Volunteer Infantry during the Civil War; from 1884 to 1888 clinical instructor in mental diseases, and from 1888 to 1898 lecturer on mental diseases in his Alma Mater; for many years in charge of the Insane Hospital, South Boston; died at his home in Belmont, Mass., October 10, aged 77.

George Edward Gavin, M.D. Louisville (Ky.) Medical College, 1896; a Fellow of the American Medical Association; and a well-known surgeon of Mobile, Ala.; died in that city, November 14, after a long illness from malignant disease of the bladder and liver, aged 43. At a meeting of the Mobile County Medical Society, November 14, it was decided that the members attend in a body the funeral of Dr. Gavin.

Brigadier General Peter J. A. Cleary, U. S. A. (retired), L.R.C.S. Eng., 1860; a veteran of the Civil War in which he served as Assistant Surgeon and Surgeon of U. S. Volunteers; a member of the Medical Corps of the Army from 1867 until his retirement in 1903; died at his home in Chattanooga, Tenn., November 5, from heart disease, aged 74.

Charles Irving Stotelmeyer, M.D. University of Maryland, Baltimore, 1892; of Hagerstown, Ind.; a member of the Indiana State Medical Association; trustee of Jefferson township; died in the Reid Memorial Hospital, Richmond, Ind., November 12, after a surgical operation, aged 55.

William Henry Robertson, M.D. University of Alabama, Mobile, 1887; a Fellow of the American Medical Association and one of the best known practitioners of southeastern Alabama; died at his home in Clayton, Ala., November 21, from valvular heart disease, aged 53.

Aaron G. Humphrey, M.D. New York Hygieo-Therapeutic College of New York, New York City, 1858; for more than half a century a practitioner of Galesburg; was for a few months a resident of Kansas City, Mo.; died at his home in that city, November 17, aged 82.

John S. French, M.D. Medical College of Indiana, Indianapolis, 1883; a veteran of the Civil War in which he served as Assistant Surgeon of the One Hundred and Twentieth Indiana Volunteer Infantry; died at his home in Pittsboro, Ind., September 19, aged 85.

Frank N. Yeager, M.D. University of Pennsylvania, Philadelphia, 1888; of Hamilton, Pa.; a Fellow of the American Medical Association; died in St. Mary's Hospital, Rochester, Minn., November 14, from peritonitis after an operation for malignant disease, aged 57.

George Washington Boyd, M.D. College of Physicians and Surgeons, Baltimore, 1895; a Fellow of the American Medical Association, and proprietor of several drug-stores in Washington; died at his home in that city, November 21, from nephritis, aged 55.

Robert M. Sadler, M.D. Louisville (Ky.) Medical College, 1877; died at his home in Okolona, Miss., November 10, from the effects of a gunshot wound of the head, self-inflicted it is believed, with suicidal intent, while despondent on account of ill health.

John Henry Grimes, M.D. University of Maryland, Baltimore, 1868; a Confederate veteran; vaccine physician of Baltimore in 1873; died at the Sheppard and Enoch Pratt Hospital, Baltimore, November 7, from arteriosclerosis, aged 72.

Charles B. Turner, M.D. University of Louisville, Ky., 1881; local surgeon of the Southern Railway at Bluemont, Va., and formerly a member of the Loudoun County Board of Health; died at his home in Bluemont, November 13, aged 56.

Charles H. Mordoff, M.D. Chicago Homeopathic Medical College, 1881; Hahnemann Medical College, Chicago, 1905; a member of the Illinois State Medical Society; died at his home in Genoa, Ill., November 16, from cerebral hemorrhage, aged 58.

Emil V. Helfferich, M.D. Medical College of Ohio, Cincinnati, 1883; of Cincinnati; died at the German Deaconess Hospital in that city, from injuries received in a jump from a window in that institution while temporarily deranged, aged 53.

Andrew Cursena Gregg, M.D. Starling Medical College, Columbus, Ohio, 1901; formerly of St. Mary's and Brookville, Pa., but more recently a resident of Chicago; died in the Englewood Hospital, November 2, from uremia, aged 45.

Joseph Morrison Tydings, M.D. Kentucky School of Medicine, Louisville, 1861; a Confederate veteran; well known as an author and philanthropist of Louisville; died at the home of his daughter in that city, November 12, aged 78.

John C. Smith, M.D. Southern Medical College, Atlanta, Ga., 1884; a member of the Medical Association of Georgia; for thirty years a resident of Carroll County, Ga.; died at his home in Mansfield, Ga., November 10, aged 64.

Ella S. Webb, M.D. Woman's Medical College of Pennsylvania, Philadelphia, 1885; managing editor of one of the publications of the Webb Publishing Company; died at her home in St. Paul, November 15, from heart disease.

Warren Vernon Grimes, M.D. Missouri Medical College, St. Louis, 1877; president of the board of health of Pacific Grove, Cal.; died at his home in that place, November 4, from cerebral hemorrhage, aged 57.

Frank Vincent Kimbrough, M.D. Vanderbilt University, Nashville, Tenn., 1893; of Maxon Mills, Ky.; local surgeon for the Illinois Central System at that place; died in Guthrie, Ky., November 6, aged 43.

Amos Davis, M.D. University of Louisville, 1874; a member of the Kentucky State and Ohio Valley medical associations; died at his home in Owensboro, Ky., November 9, from nephritis, aged 66.

George Francis Hinmers, M.D. University of Oregon, Portland, 1895; died at his home in Milwaukie, Ore., August 30, from injuries received from a fall from a wagon twelve hours before, aged 54.

Joseph Henry Kelley, M.D. Bellevue Hospital Medical College, 1884; a member of the Massachusetts Medical Society; died at his home in Worcester, Mass., November 10, from cerebral hemorrhage.

Stephen Hunt, M.D. Rush Medical College, 1881; a member of the Indiana State Medical Association; died at his home in Coatesville, Ind., November 8, from cerebral hemorrhage, aged 69.

Ben Davis, M.D. Kentucky School of Medicine, Louisville, 1908; a member of the Oklahoma State Medical Association; died at his home in Kinta, Okla., November 1, from typhoid fever, aged 31.

Frank Henry Hobbs, M.D. Medical School of Maine, Brunswick, 1900; a member of the Maine Medical Association; died at his home in Waterboro, Me., October 11, aged 55.

Cassius Emmet Van Matre, M.D. Miami Medical College, Cincinnati, 1895; a Fellow of the American Medical Association; died at his home in Newcastle, Ind., October 17, aged 44.

Eugene V. West, M.D. Meharry Medical College, Nashville, Tenn., 1892; a colored practitioner of Tampa, Fla., for twenty-two years; died at his home in that city, November 5, aged 45.

Isaac R. Dunning, M.D. Eclectic Medical Institute, Cincinnati, 1867; Rush Medical College, 1870; died at his home in Benton Harbor, Mich., August 19, from cardiac asthma, aged 71.

Francis M. Wilson, M.D. Louisville (Ky.) Medical College, 1884; a member of the Florida Medical Association; died at his home in Bartow, Fla., November 8, from heart disease, aged 55.

Jerome R. Lyon, M.D. Rush Medical College, about 1867; for forty-five years in active practice; died at his home in Excelsior Springs, Mo., October 1, from pneumonia, aged 91.

Frederick Leander Davis, M.D. Medical School of Maine, Brunswick, 1888; a member of the Maine Medical Association; died at his home in Biddeford, Me., October 9, aged 55.

William Blair, M.D. University of Louisville, Ky., 1875; a member of the Kentucky State Medical Association; died at his home in Glens Fork, Ky., November 12, aged 73.

Andrew Benjamin Bookins, M.D. University of Louisville, Ky., 1875; a practitioner since 1856; died in Jacksonville, Fla., September 21, from chronic nephritis, aged 80.

Lindley Ruddick, M.D. University of Louisville, Ky., 1882; a member of the Indiana State Medical Association; died at his home in Seymour, Ind., October 20, aged 70.

Eugene J. Hickey, M.D. University of Vermont, Burlington, 1907; a member of the Vermont State Medical Society; died at his home in Warren, Vt., October 7.

Samuel H. Smyth, M.D. New York Homeopathic Medical College, 1880; died at his home in New York City, November 1.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

WINE OF CARDUI

The Holston Conference of the Methodist Church Endorses this Fraudulent Nostrum

Ordinarily, The Journal would not consider giving the Wine of Cardui fraud and its exploiters any further publicity in these pages. Wine of Cardui, however, is again brought into the lime-light because of the action of its friends and beneficiaries. In this case, its friends are the official committee appointed by the Quarterly Conference of the First Methodist Church of Chattanooga, to which J. A. Patten, chief owner of the Wine of Cardui concern, belongs and the Holston Conference which officially accepted the "findings" of the committee.

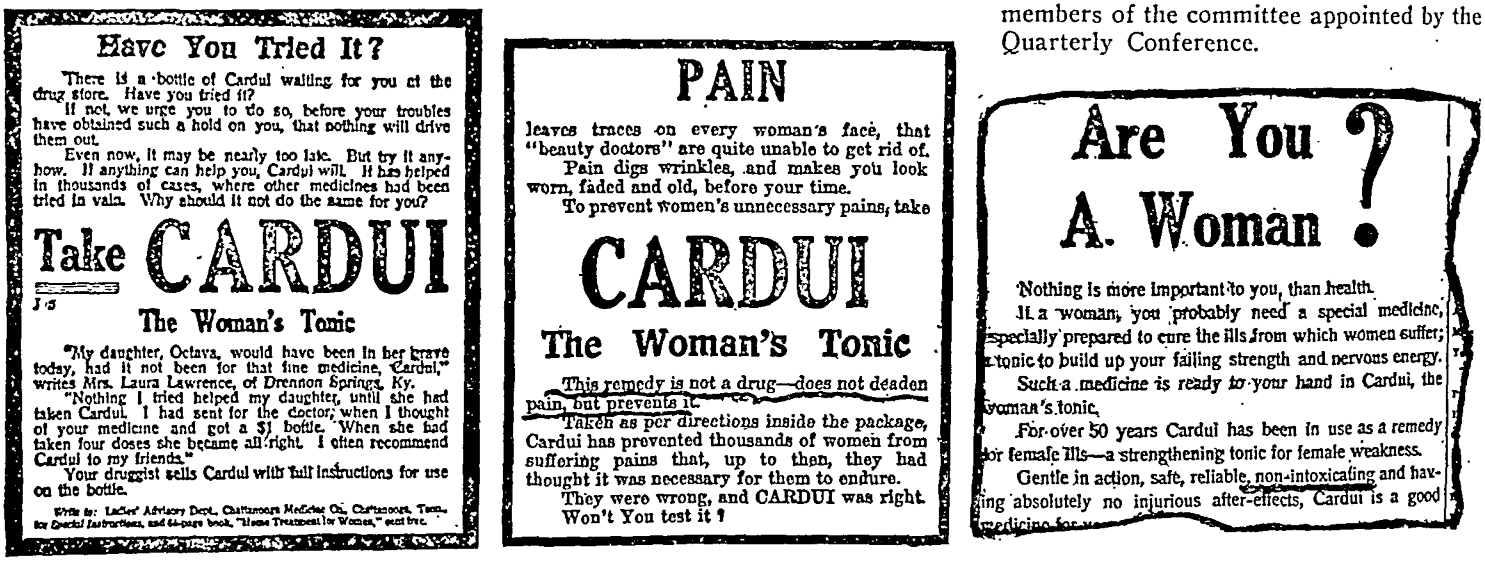
We cannot state too emphatically that what follows is in no sense a criticism of the Methodist Episcopal Church. Letters we have received from earnest Methodists lead us to believe that the membership of that church, generally, takes the same attitude toward Wine of Cardui that The Journal has taken. *We would also* reiterate that nothing that has been said, or that may be said in the future, regarding John A. Patten is actuated by malice. The Journal has in mind not Mr. Patten, not the Chattanooga Medicine Company, not the Methodist Episcopal Church, but the thousands of sickly women over the country—and especially those in the South—who have been and are being cruelly deceived in the purchase of a fraudulent nostrum.

To the initiated, the idea of Mr. Patten or his business being critized in his own locality is sardonically humorous. The man is such a power in his own city and state that the outcome of any local "investigation" is a foregone conclusion. Nevertheless, the local committee made an "investigation" and the Chattanooga *Times* gave a very full account of its "findings." The matter in the *Times* has been reprinted in leaflet form and mailed from Post Office Drawer B, St. Elmo Station, Chattanooga, Tenn. This is the "return address" that appears on the envelopes in which letters are sent out by the "Ladies Advisory Department" of the Chattanooga Medicine Company.

WHAT SOME METHODISTS THINK

Before discussing the report of the committee, as published in the Chattanooga *Times*, the following facts are worth noting: John A. Patten is a member of the First Methodist Church of Chattanooga. The pastor of that church is—or was—Rev. C. H. Myers. Although no statement has been made by Mr. Myers regarding his opinion of John A. Patten, the most prominent member of his church, he does not appear to be in sympathy with either the methods by which Mr. Patten made his money or the influence which this *money exercises in the church.* After The Journal had exposed the Chattanooga Medicine Company's fraudulent business, Mr. Myers wrote Mr. Patten a personal letter—which has recently been made public—suggesting that it might be for the best interests of all concerned if he, Patten, would turn over the teaching of the men's bible class to some one else. In addition, Mr. Myers has openly protested against what he called the undemocratic power that was being exercised in the church.

A Chattanooga paper in reporting a statement made by Rev. Dr. Myers to the members of his church said: "Without becoming personal, he [Mr. Myers] condemned the leading members of the church, declaring they recognize money as the greatest power extant." A little later Mr. Myers nominated the stewards for his church. According to the newspaper reports at the time he "eliminated ten friends of John A. Patten *from* the Board of Stewards." The names of the "friends" who had been eliminated were given in the paper. It is worth noting that among these "friends" were three of *the six whose names go to make up the committee that put* its official O K on Mr. Patten and his business. These three were, respectively, the chairman, secretary and one of the members of the committee appointed by the Quarterly Conference.



Have You Tried It?

There is a bottle of Cardui waiting for you at the drug store. Have you tried it?

If not, we urge you to do so, before your troubles have obtained such a hold on you, that nothing will drive them out.

Even now, it may be nearly too late. But try it anyhow. If anything can help you, Cardui will. It has helped in thousands of cases, where other medicines had been tried in vain. Why should it not do the same for you?

Take CARDUI

The Woman's Tonic

"My daughter, Octava, would have been in her grave today, had it not been for that fine medicine, Cardui," writes Mrs. Laura Lawrence, of Drennon Springs, Ky.

"Nothing I tried helped my daughter, until she had taken Cardui. I had sent for the doctor, when I thought of your medicine and got a $1 bottle. When she had taken four doses she became all right. I often recommend Cardui to my friends."

Your druggist sells Cardui with full instructions for use on the bottle.

Write to: Ladies' Advisory Dept., Chattanooga Medicine Co., Chattanooga, Tenn., for Special Instructions, and 64-page book, "Home Treatment for Women," sent free.

PAIN

leaves traces on every woman's face, that "beauty doctors" are quite unable to get rid of.

Pain digs wrinkles, and makes you look worn, faded and old, before your time.

To prevent women's unnecessary pains, take

CARDUI

The Woman's Tonic

This remedy is not a drug—does not deaden pain, but prevents it.

Taken as per directions inside the package, Cardui has prevented thousands of women from suffering pains that, up to then, they had thought it was necessary for them to endure.

They were wrong, and CARDUI was right.

Won't You test it ?

Are You A Woman?

Nothing is more important to you, than health.

If a woman, you probably need a special medicine, especially prepared to cure the ills from which women suffer; a tonic to build up your failing strength and nervous energy.

Such a medicine is ready to your hand in Cardui, the woman's tonic.

For over 50 years Cardui has been in use as a remedy for female ills—a strengthening tonic for female weakness.

Gentle in action, safe, reliable, non-intoxicating and having absolutely no injurious after-effects, Cardui is a good

Some advertising (greatly reduced) issued in 1910—some years after John A, Patten admittedly controlled the business.

In the latter part of October the Holston Conference met in Cleveland, Tenn. One of its first official acts was to "accept" the Quarterly Conference's "exoneration" of Mr. Patten and his business. Moreover, when the conference had finished making its appointments, it was found that the Rev. C. H. Myers had been removed from the pastorate of the First Methodist Church, and had been assigned to an inferior position in another city, a position that he refused to accept. Mr. Myers, in a letter published in the Chattanooga *Times*, commenting on the action of the conference, said in part:

> "We have lost locally in our fight for a high principle, but the whole church will yet know and believe that such a bureaucratic system of church government cannot long exist as a power for righteousness. We are standing against a gigantic ecclesiastical machine, fed by an unlimited amount of money. Mammon has won."

ANOTHER MINISTER PROTESTS

Mr. Patten's pastor-that-was is not, however, the only churchman who has spoken against the sinister *effect* that Wine of Cardui money exerts on the Methodist Episcopal Church. Rev. G. T. Byrd, pastor of the First Methodist Church of Etowah, Tenn., (also in the *Holston Conference*) as long ago as last July arraigned the administration of that Conference. In a letter sent to the members of his conference and which a Chattanooga paper published *in* full under the sub-heading "Thinly Veiled Attack on J. A. Patten," Mr. Byrd charged among other things:

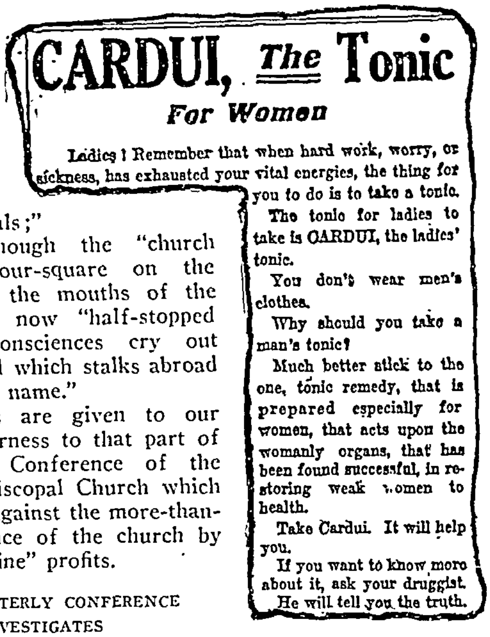
1. That the bishops seem to have "sacrificed their high sense of righteousness by accepting the influence of tainted money;"

2. That it was well-known and generally accepted "that the policies and appointments of the conference have had to have the endorsement of one prominent layman" before they were carried out;

3. That the church "is not dependent for its life and growth on the use of tainted money—money which comes from a product which government analysis shows to be 20 per cent. alcohol and which has frequently been condemned by medical journals;"

4. That although the "church has stood four-square on the liquor traffic" the mouths of the members are now "half-stopped while our consciences cry out against alcohol which stalks abroad under another name."

These facts are given to our readers in fairness to that part of the Holston Conference of the Methodist Episcopal Church which is protesting against the more-than-local dominance of the church by "patent medicine" profits.



CARDUI, *The* Tonic

For Women

Ladies! Remember that when hard work, worry, or sickness, has exhausted your vital energies, the thing for you to do is to take a tonic.

The tonic for ladies to take is CARDUI, the ladies' tonic.

You don't wear men's clothes.

Why should you take a man's tonic?

Much better stick to the one, tonic remedy, that is prepared especially for women, that acts upon the womanly organs, that has been found successful, in restoring weak women to health.

Take Cardui. It will help you.

If you want to know more about it, ask your druggist. He will tell you the truth.

Advertisement (greatly reduced) published in 1910. Wine of Cardui is the "ladies' tonic" — now; but some years ago the circular around each bottle of Wine of Cardui read: "IT HAS ALSO PROVED TO BE A FINE TONIC FOR MEN IN RESTORING WASTED ENERGIES."

THE QUARTERLY CONFERENCE INVESTIGATES

Now to refer to the "investigation" made by the official committee appointed by the Quarterly Conference of the First Methodist Church of Chattanooga. The committee was unanimously of the opinion, "after deliberate consideration," that in spite of the admitted fact that one-fifth of every bottle of Wine of Cardui is pure alcohol, yet, this is the only way in which the "drug content of the remedy" can be administered. Had there been an expert chemist or pharmacist on the committee he could have told them that it was unnecessary to use any alcohol. If the vegetable material is the part of the nostrum that possesses the marvelous qualities claimed for it, the drugs could be put up in tablet or pill form. The committee was further "satisfied" with a statement ascribed to druggists who had "never heard of its being used as a tipple or booze or used habitually." Self-respecting druggists—probably the class called on—would not, of course, be likely to know of the misuse of this preparation. The report does not indicate that any testimony was sought from the proprietors of country "general stores." In any case, was this committee innocent enough to expect the retailers of this alcoholic nostrum to admit that they had sold the stuff in quantities, or for purposes that were not legitimate?

PRESCRIBING ALCOHOL

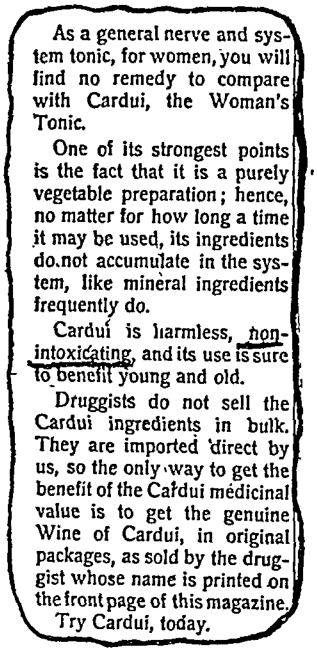
The committee was further "satisfied" with the argument—also alleged to have been given by druggists—that many remedies commonly prescribed by physicians to sick women contain a much larger percentage of alcohol than does Wine of Cardui. It is, of course, doubtless true that there are some physicians who prescribe drugs unscientifically and absurdly. To this fact THE JOURNAL has called attention for years, and has devoted much more space to and placed more emphasis on this very evil than it has devoted to "patent medicine" frauds. That the modern, educated physician is in the habit of prescribing alcohol for sickly women is, however, a question that would have to be settled on better evidence than that presented through the Chattanooga committee. Even if it were true, though, what would it signify? Because a physician prescribes a few doses of an alcoholic tincture to a patient whose physical condition is known to him and who is under his immediate supervision and control, is that any justification for a "patent medicine" concern recommending a nostrum having alcohol as its essential constituent, to persons they have never seen and the nature of whose ailments they do not, and could not, understand? To argue that because dangerous drugs are prescribed by physicians such drugs may legitimately be sold indiscriminately, is absurd. Because dynamite and blasting powder are used by, and sold on the order of, mining experts and civil engineers is no excuse for permitting every country store to sell dynamite and blasting powder to anyone it sees fit.

"EVIDENCE" OF CURES

The committee further reported that it found "abundance of evidence to inspire in the manufacturers" of Wine of Cardui the belief that it "cures" the ailments for which it is recommended to the public. What this evidence was the committee did not disclose. The absurdity and futility of a group of laymen (there were no physicians on the committee so far as the report indicates) passing on questions of therapeutic efficiency, is self-evident. Presumably, the committee read the various testimonials that form so large a part of the Chattanooga Medicine Company's advertising material. It might be suggested at this point that the same committee could have found equally abundant evidence to prove the prophylactic powers of the left hind foot of a rabbit caught in a churchyard in the dark of the moon! And this evidence would have just the same scientific value as that of the average testimonial for Wine of Cardui or any other nostrum or method of treatment.

THE NOSTRUM MAKER'S SHEET ANCHOR—MYSTERY

In answer to THE JOURNAL'S charge that nothing having therapeutic effects could be found in Wine of Cardui other than the alcohol, the committee says that it was "shown many authorities to the effect that it is very difficult for any chemist to analyze a vegetable compound such as this and be sure of its contents." The old, old argument of the nostrum exploiter—mystery! While technically it may be true that there are some vegetable extractives whose identity cannot be positively determined by chemical analysis, it is equally true that the active ingredients of practically every substance having any medicinal property can be identified. The fact that the chemist cannot name all of the plant extractives that enter into a nostrum such as Wine of Cardui, is of no practical importance. The essential drug in this nostrum is the alcohol, and it is the only drug demonstrably present in sufficient quantities to give any appreciable therapeutic effect.



As a general nerve and system tonic, for women, you will find no remedy to compare with Cardui, the Woman's Tonic.

One of its strongest points is the fact that it is a purely vegetable preparation; hence, no matter for how long a time it may be used, its ingredients do not accumulate in the system, like mineral ingredients frequently do.

Cardui is harmless, non-intoxicating, and its use is sure to benefit young and old.

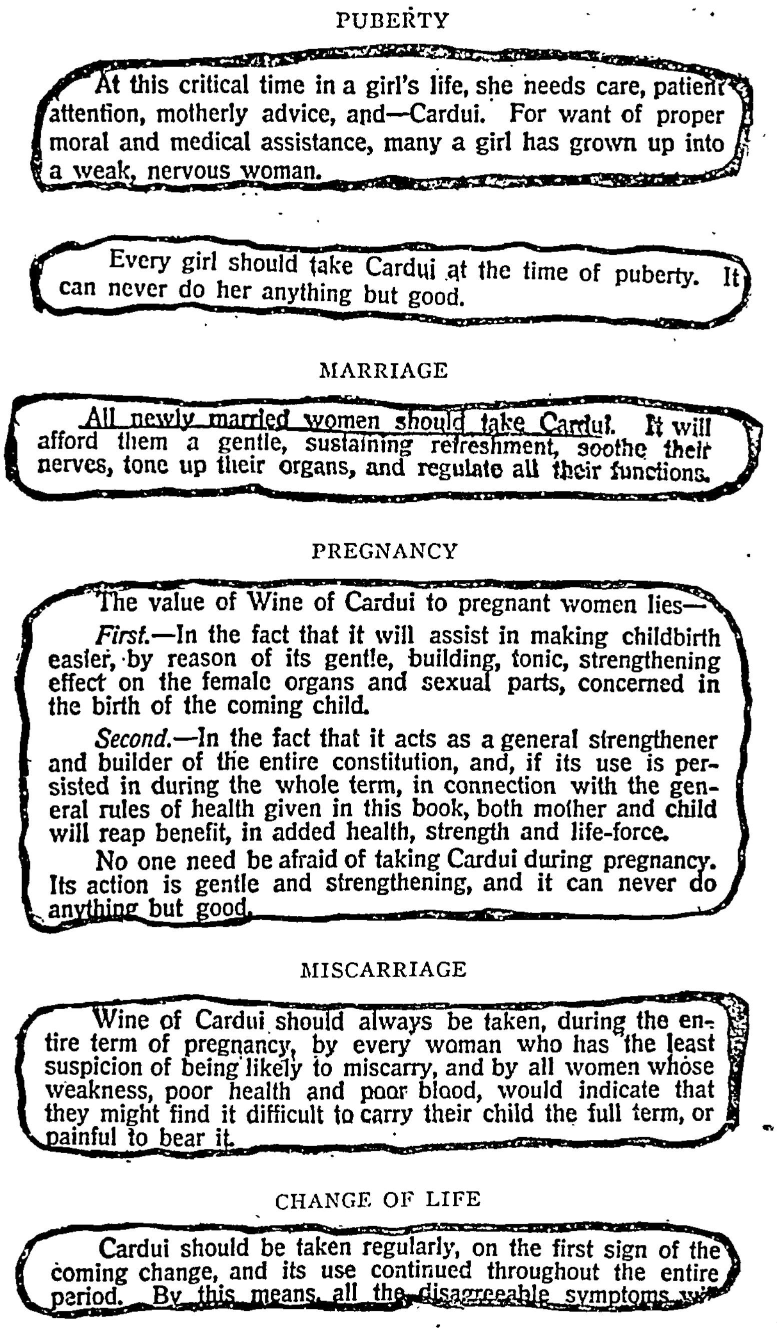
Druggists do not sell the Cardui ingredients in bulk. They are imported direct by us, so the only way to get the benefit of the Cardui medicinal value is to get the genuine Wine of Cardui, in original packages, as sold by the druggist whose name is printed on the front page of this magazine.

Try Cardui, today.

Advertisement (reduced) published 1910. Read it carefully and then ask whether THE JOURNAL is justified in criticizing Wine of Cardui and its exploiters.

PATTEN'S ADVERTISING

In discussing THE JOURNAL'S criticisms of the Wine of Cardui advertising, the committee stated that there were two classes of advertising that had been criticized, (1) that which was printed before Mr. Patten took charge of the company and (2) that which was found in a book entitled, "Home Treatment for Women." This statement is but a half-truth. THE JOURNAL presented advertisements that had been published years after Mr. Patten had admittedly been in control, in addition to the claims that were made for the nostrum in the "Home Treatment for Women" booklet. The Journal went further. It gave photographic reproductions of the advertisements with a statement beneath each calling attention to the date on which the advertisements appeared! One of these reproductions was of an advertisement which in large, blackfaced type urged "young girls" to take Wine of Cardui. It contained the statement that Wine of Cardui is "non-intoxicating." This untruth used to appear on the Wine of Cardui labels in the days before the Food and Drugs Act was passed and it continued to appear in the circular around the bottle for some time after the Food and Drugs Act was passed.[1] It contained the further statement that Wine of Cardui is "perfectly harmless" — another lie that appeared on the label before the Food and Drugs Act was passed. Had the committee been more intent on giving the public a plain unvarnished statement of facts regarding the methods of the Wine of Cardui concern than it was, apparently, in wielding the "whitewash brush," it could have found many other fraudulent claims made for the nostrum other than those that The Journal has brought out.



PUBERTY

At this critical time in a girl's life, she needs care, patient attention, motherly advice, and—Cardui. For want of proper moral and medical assistance, many a girl has grown up into a weak, nervous woman.

Every girl should take Cardui at the time of puberty. It can never do her anything but good.

MARRIAGE

All newly married women should take Cardui. It will afford them a gentle, sustaining refreshment, soothe their nerves, tone up their organs, and regulate all their functions.

PREGNANCY

The value of Wine of Cardui to pregnant women lies—

First.—In the fact that it will assist in making childbirth easier, by reason of its gentle, building, tonic, strengthening effect on the female organs and sexual parts, concerned in the birth of the coming child.

Second.—In the fact that it acts as a general strengthener and builder of the entire constitution, and, if its use is persisted in during the whole term, in connection with the general rules of health given in this book, both mother and child will reap benefit, in added health, strength and life-force.

No one need be afraid of taking Cardui during pregnancy. Its action is gentle and strengthening, and it can never do anything but good.

MISCARRIAGE

Wine of Cardui should always be taken, during the entire term of pregnancy, by every woman who has the least suspicion of being likely to miscarry, and by all women whose weakness, poor health and poor blood, would indicate that they might find it difficult to carry their child the full term, or painful to bear it.

CHANGE OF LIFE

Cardui should be taken regularly, on the first sign of the coming change, and its use continued throughout the entire period. By this means, all the disagreeable symptoms w

Photographic reproductions (reduced) from the booklet "Home Treatment for Women," sent out early this year (1914). After The Journal's exposé a denatured edition of this booklet was issued.

Mr. Patten claims to have assumed control of the Wine of Cardui business in 1905, and he insists that the business should be judged according to the advertising issued since that time. This is exactly what The Journal has done. The advertising which The Journal has criticized most severely is that which was being issued in 1914; other claims just as fraudulent were reproduced from advertisements published in 1910—five years after Mr. Patten admits he assumed control. But the attempt of Mr. Patten to dodge behind a technicality, while in keeping with the tactics of "patent-medicine" fakers, is not such as to inspire respect for him or his business in the eyes of decent people. We have evidence to show that Mr. Patten was placing Wine of Cardui advertisements years before he assumed open control. Certain it is that Mr. Patten was connected with, and a beneficiary of, the Wine of Cardui business many years before his admitted complete control. He was receiving money from this wretched business when the advertising was vile, loathsome and indecent.

But as Mr. Patten has claimed that since he assumed charge the advertising has been "free from curative claims that could be regarded as extreme or subject to any fair criticism," let us quote some more:

> ". . . of the utmost value in relieving pain, regulating the menses, curing leucorrhea, preventing miscarriage and making childbirth easy." [*Claim made in 1909.*]
>
> "It is a reliable, scientific, non-intoxicating, harmless medicine for all females, at puberty, maturity, pregnancy and during the change of life." [*Claim made in 1909.*]
>
> "No matter how serious or long standing the trouble Cardui will help you. It is a mild vegetable tonic remedy especially adapted to relieve and cure the common womanly ailments." [*Claim made in 1912.*]
>
> "For young girls just entering into womanhood and young ladies whose life duties have not long begun, Cardui is often of vital importance, giving them strength for daily tasks." [*Claim made in 1910.*]
>
> "It [Cardui] is a pure non-intoxicating preparation . . ." [*Claim made in 1910.*]
>
> "Its ingredients help build up vitality, tone up the nerves and strengthen the entire womanly constitution. It is mild and harmless." [*Claim made in 1914.*]
>
> "This remedy [Cardui] is not a drug—does not deaden pain, but prevents it." [*Claim made in 1910.*]
>
> "Cardui acts on the cause of the disease [Vaginitis] and is therefore not a mere palliative, but a scientific and specific remedy, with a curative effect upon the seat of the trouble." [*Claim made in 1914.*]
>
> "Cardui acts medicinally on the ovaries and tubes, and on all their surrounding parts, gradually subduing the inflammation, stopping pain and relieving the congestion." [*Claim made in 1914.*]
>
> "Cardui is harmless, non-intoxicating . . ." [*Claim made in 1910.*]
>
> "As a general nerve and system tonic for women, you will find no remedy to compare with Cardui, the Woman's Tonic." [*Claim made in 1910.*]

THE JOURNAL'S ALLEGED "STRAINED INTERPRETATIONS"

The above are some of the claims made by the Chattanooga Medicine Company for Wine of Cardui *since* Mr. Patten has admittedly had charge of affairs. As to the other claims quoted in The Journal's article, taken from the booklet, "Home Treatment for Women" (sent out in 1914), these the committee gloss over with the admission that while their "phraseology" is "careless" The Journal's "interpretation" of the statements is "strained." Was it strained? The Journal called attention to the fact that women are urged to take Cardui for "hanging breasts." Let us quote the entire paragraph so that our readers can determine whether or not our interpretation is strained:

> "At the least tenderness, soreness, swelling, discharge of milk-like fluid, *lack of tone, shown by hanging breasts,* or change in the color of the areola, not caused by pregnancy, *it is time to take Cardui.*" [Claims made 1914. Italics ours.—Ed.]

The Journal said that Mr. Patten's company recommended this alcoholic nostrum for gonorrheal infection of the vulva; was it justified in so saying? Again, let the matter be quoted in full:

> "Local diseases of the vulva are, principally, heat, inflammation and itching, and are frequently caused by want of cleanliness. Very often, however, *they are caused by gonorrheal infection,* or by disease of the

---

[1] For some time after the passage of the Food and Drugs Act, many "patent medicine" makers held that the circular around the bottle did not come within the scope of the Act. Hence, while they deleted the lies from the *labels* of their nostrums, they continued to falsify in the *circulars* wrapped around the bottles. The history of the "patent medicine" business shows that the average nostrum maker will lie just so long as he can do it with safety.

womb, ovaries, or vaginal canal, which causes irritating and poisonous secretions.

"*Cardui will exert marked beneficial effect upon this local irritation*, by relieving the inflammation which causes it; but, in addition to general treatment, local treatment should also be carefully carried out, the outer parts washed with castile or palm oil soap and warm water, and well dried, at least once a day, after which a little powdered boracic acid may be dusted on." [Claims made 1914. Italics ours.—Ed.]

Are You Below Par?

Take CARDUI

The Woman's Tonic

Mrs. Weaver was Below Par

Sold By all Druggists

This advertisement appeared in October, 1911. In the original it measured 11 inches by 10 inches.

The Journal further said that Wine of Cardui was recommended for suppressed menstruation and also for "flooding." Was it justified in saying so? Again let us quote:

> "Besides the two special forms of menstrual disorder described above [*amenorrhea* and *menorrhagia*], there may be, as stated, others, such as *scantiness, irregularity* of the functions, painful periods, etc., *all of which can nearly always be cured by persistent treatment with Cardui*." [Claims made 1914. Italics ours.—Ed.]

The Journal said, too, that Mr. Patten's concern recommended that all newly married women should take Cardui. Was the "interpretation" in this case "strained?" Let us quote in full:

> "*All newly married women should take Cardui*. It will afford them a gentle, sustaining refreshment, soothe their nerves, tone up their organs, and regulate all their functions." [Claims made 1914. Italics ours.—Ed.]

The Journal also accused the Chattanooga Medicine Company of making the villainous suggestion that every girl should take Cardui at the time of puberty. Was this accusation just?

> "At puberty, the girl blossoms out like a flower from the opening bud. Her figure becomes fuller and rounder; her busts swell, and are often sore and tender; her voice becomes sweeter; hair begins to show itself under the armpits and on the lower abdomen.
>
> "*At this critical time in a girl's life, she needs* care, patient attention, motherly advice, and—*Cardui*. For want of proper moral and medical assistance, many a girl has grown up into a weak, nervous woman . . ."
>
> "*Every girl should take Cardui at the time of puberty*. It can never do her anything but good." [Claims made 1914. Italics ours.—Ed.]

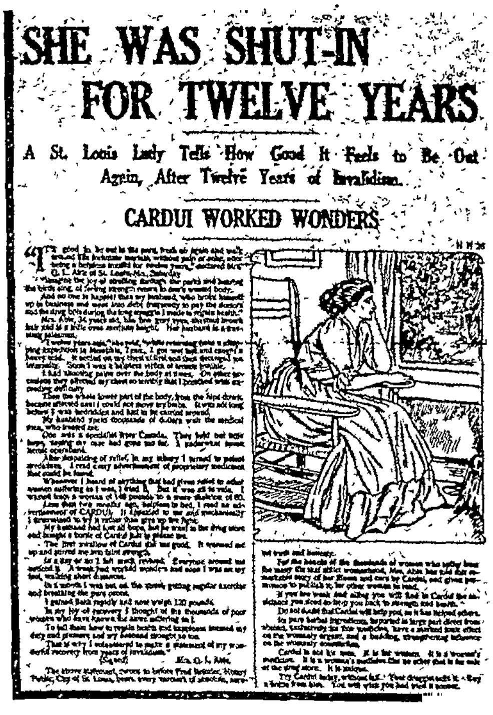
We could, if space permitted, show in detail that the charges of The Journal against the claims made for Wine of Cardui were in every instance understated rather than overstated; that The Journal's "interpretation" of the claims made by the Chattanooga Medicine Company instead of being "strained" was, in fact, more than justified.

Lastly, the committee decided that the owners of the Chattanooga Medicine Company were not morally culpable and "there could be no basis for any such charge unless it was shown that the medicine is worthless." As a matter of fact, even if Wine of Cardui had valuable drugs in it, the fraudulent claims under which it has been sold would still render its exploiters morally culpable. The committee summed up its findings with the statement that its investigation disclosed nothing which, in its opinion, "would prevent an intelligent and conscientious man" from engaging in the Wine of Cardui business, "from the point of view of either morals or religion." In other words, the Quarterly Conference of the First Methodist Church of Chattanooga—the Holston Conference, concurring—sees nothing either immoral or irreligious in the sale of a nostrum whose essential constituent is alcohol; sees nothing immoral or irreligious in the exploitation, under fraudulent claims, of this preparation to every adolescent girl, to every bride, to every expectant mother and to every woman at the menopause!

As we have said before, The Journal does not believe that this local official "whitewashing" is representative of the views of the majority, or of any substantial minority, of the members of the church in which Mr. Patten plays such an important part. It is true that a certain part of Methodist officialdom is standing up for Patten and his wretched business. Some of the *Christian Advocates* have come, editorially, to Mr. Patten's rescue, urging their readers to suspend judgment until Patten's suit for libel against The Journal has been decided. But Mr. Patten, it should be remembered, is chairman of the Book Committee which (1) annually fixes the salaries of all official editors, which (2) has power to discontinue any official Methodist publication, and which (3) has, in fact, "general supervision and direction of the publishing interests" of the church. These facts should, in fairness, be remembered in extenuation of the action of those editors who come so valiantly to the defense of the manufacturer of Wine of Cardui.

WHY REJECT ADVERTISEMENTS OF WINE OF CARDUI

On the other hand it must again be emphasized that no official publication of the Methodist Episcopal Church accepts the advertisements of Wine of Cardui! Yet if Wine of Cardui can do half that Mr. Patten's company has claimed for it, it can accomplish more than any preparation known to medical science. If it can exert "beneficial effect" in gonorrheal vulvitis; if it is a "specific remedy" in gonorrheal vaginitis; if it has "cured" the wombs of "over a million women;" if it can "nearly always" "cure" amenorrhea, menorrhagia, "scantiness, irregularity of the functions, painful



SHE WAS SHUT-IN FOR TWELVE YEARS

CARDUI WORKED WONDERS

Another advertisement published in 1911. The original occupied more than 150 square inches of space.

periods, etc.;" if it is what every girl at puberty "needs;" if it is something that "all newly married women should take;" if it "will assist in making childbirth easier;" if it is something the lying-in woman should take "two or three times a day;" if the woman at the menopause should take and continue its use "through the entire period"—if these are the powers and the potentialities of Wine of Cardui, then indeed are the Methodist publications remiss *in their* duty to humanity. If this nostrum possesses the powers claimed for it—claims which two Methodist conferences have accepted as reasonable and true—then the editors of the various *Christian Advocates* are derelict in not accepting advertisements of the product of the Chairman of their Book Committee—Wine of Cardui, The Woman's Tonic.

Correspondence

Do Patent Medicines Control the Press?—An Example

To the Editor:—Any suggestion that the daily press is subservient to dishonest advertising interests is received with instant and fervid indignation by 95 per cent. of the newspapers. Just about this percentage takes money for obviously crooked advertising, in the form of quack medical "copy." As the object of much of this virtuous journalistic wrath on account of my recent novel "The Clarion," I wish to point out an instance in the career of the book itself which curiously supports my contention.

Binghamton, N. Y., is the home of Swamp Root, a conspicuous "booze-medicine" which I exposed a few years ago in *Collier's Weekly*. It is a prosperous and thriving city of almost 55,000 inhabitants, served by two local newspapers, the *Press* and the *Republican-Herald*. Just before the appearance of "The Clarion," the publishers sent to the *Press* an advertisement of the book specially designed to arouse the local interest of a city largely devoted to the patent medicine industry. The copy was returned with the following letter:

> Binghamton, N. Y., Sept. 30, 1914.
>
> Houghton Mifflin Company, 4 Park St., Boston, Mass.
>
> *Gentlemen:*—We are returning, herewith, your order of the 28th inst., for "The Clarion" with copy, as we do not care to handle same. Thanking you for the proposition, we are
>
> Very truly yours,
> The Binghamton Press.

On the theory that this particular form of wording had been deemed too pointed, one of the regular advertisements of the book was sent. This also was refused, with the following suggestive intimation:

> Binghamton, N. Y., Oct. 9, 1914.
>
> Houghton Mifflin Company, 4 Park St., Boston, Mass.
>
> *Gentlemen:*—We are returning, herewith, your copy of the 7th inst., for "The Clarion." We greatly prefer not to handle any advertising for this particular book. Thanking you for the offer, we are
>
> Very truly yours,
> The Binghamton Press.

As the *Press* had formerly been owned by the Kilmers, proprietors of Swamp Root, its indisposition to advertise a work dealing with the proprietary medicine evil might be attributed to a legacy of loyalty to old standards. No such inhibition would apply to the *Republican-Herald*. The first, or local advertisement was sent to that office, bringing with it tribulation of spirit to the business staff. They did not like to reject the advertising. All newspapers particularly appreciate publishers' business, as a mark of "class." But they felt evidently that the proffered "copy" was too near home, and they wrote asking if it could not be modified somewhat. Thereupon the regular stock advertisement of the book was forwarded. What occurred in the office in the meantime is a matter of conjecture only. But the outcome is sufficiently significant. "Owing to a peculiar agreement existing between the Binghamton newspapers" (I quote from the letter of the advertising agency acting for the publishers) the *Republican-Herald* felt compelled to decline all advertising of this particular book!

Meantime the local book-stores refused to order it, although it was having one of the largest advance sales of the year in other parts of the country. One store made no secret of the fact that fear of the Swamp Root interests kept the novel off their shelves. It was not even obtainable at the local public library. Since this letter was written, however, I understand that the library has put it in, and the book department of a general merchandise store which at first rejected it, is now carrying the book.

All of which would seem to indicate that my fictional city of "Worthington" with its press under the domination of "our leading citizen," Dr. Surtaine of "Certina" fame, is not perhaps so wholly absurd and foundationless as the New York *Times*, the San Francisco *Chronicle* and others of the noble band of newspaper defenders would have their public believe.

Samuel Hopkins Adams, Auburn, N. Y.

Shields in Vaccination

To the Editor:—Will you give me space in The Journal in which to protest against the still too frequent use of "shields" in covering vaccination wounds? In routine vaccination work it has recently been my lot to examine many arms, a number of which I have dressed after the persons had applied shields, on their own initiative, or often on the advice of some physician. Others, having large, ugly cicatricial evidence of former pyogenic infection, too frequently give a history of having worn shields. I have removed shields and have seen a collection of accumulated pus roll down the arm, the patient thinking this a natural result of the "take." Shields are usually perforated for supposed ventilation, the perforation in reality serving to admit germ-laden dust and dirt of various kinds. The shield prevents cleansing of the wound, and gives the patient a false sense of proper protection. There is not a doubt that shields have been the direct cause of many seriously infected arms, thus in many instances causing the public to antagonize a most valuable prophylactic procedure. Shields are an abomination and a danger, and I should like to suggest that they be made a subject for comment in your department of Propaganda for Reform. They are far more dangerous than many patent medicines, as the latter are often harmless in themselves, while the former are a source of danger. It should be impressed on the profession, and the public, that a vaccination wound should have the same carefully applied sterile dressing as any other wound or sore, and that such dressing is much cheaper and simpler. These shields are manufactured by reputable firms who would, no doubt, refrain from placing them on the market if sufficient effort were made by clinicians to impress the makers with a knowledge of their dangers.

Alfred G. Farmer, M.D.,
Colon Hospital, Cristobal, C. Z.

Danger of War News

To the Editor:—It is time the medical profession impressed on the public the danger arising from too much reading and thinking of the war and its tragedies. Consideration of the vastness of the war, with its unnumbered and unspeakable atrocities and its suffering, overstimulates and weakens the mental fiber, and this soon reacts on the physical state of the individual. The husband neglects his wife, the mother her child, sleep is lost, appetite and digestion are impaired by reading of Belgium and blood, Prussia and pillage, Germany and guns, Servia and shrapnel, cholera, ruins, rape, hunger, cold, wounds, widows, orphans, destruction, despair, drunkenness and death. Daily the press of the country places before our greedy eyes all the printable horrors, and as we grasp our paper we breathe a curse or prayer according to the tenor of the latest despatch. The danger of this is increased by the constantly changing results of the vital conflict. The rapid shift from overstimulation of our emotions to deep depression causes increased blood-pressure, cerebral congestion, nervousness and irritability and may lead to imagined or real physical degeneration. Also it is to be remembered that the constant and earnest reader, especially he who is naturally emotional or neurotic, suffers from this overstimulation and depression for an indefinite time. The excitement and depression is quite different from that bred of a horse race or prize fight, in which our emotions undergo rapid change for only a short time, and yet we know that cases of collapse and even sudden death have occurred at such events. The ending of the present war may be far in the future, and the harrowing conditions of our fellow men meanwhile will probably become more extreme and more pitiable, while it may be that our doubts and depressions will become more marked. Another bad influence is the uncertainty of the reports we hear, so that we are exposed to frequent and swift revulsions of feeling, uplifts and downthrusts of the mental scale. As a matter of fact, we suffer far more from apprehension of doubt of the issue of events than from the event itself; in the present instance, moreover, our mental impressions are so chaotic that confusion is caused by the simple process of attempting to grasp what is going on.

What we need now especially is to conserve our energy and stop this fretting, worrying, nerve-racking and useless occupation of reading and discussing harrowing details. Each of us should look at this terrible thing soberly, quietly and broadly, not allowing an emotional element to enter the subject; for so soon as we do, our good judgment and balance is sent tumbling toward hysteria and nerve exhaustion. GURNEY WILLIAMS, M.D., Atlantic City, N. J.

The Cammidge Reaction in the Urine—Dextrinuria

To the Editor:—In THE JOURNAL, Oct. 31, 1914, p. 1581, which has just reached me, you comment on an article by Pekelharing and Van Hoogenhuyze (*Ztschr. f. physiol. Chem.*, 1914, xci, 151) on this subject and state that these observers suggest that the reaction is due to a dextrinuria. May I point out that in a paper which I read before the Medical Section of the Seventeenth International Congress of Medicine in London in August, 1913, on a quantitative method of performing the so-called "pancreatic" reaction, I stated that the reaction is due to the presence of a substance "intermediate between sugar and glycogen," thus hinting at its being a dextrin? Shortly afterward I was able to complete the evidence and, in conjunction with my chemical assistant, Mr. Howard, I wrote a paper entitled "Observations on the Composition and Derivatives of Urinary Dextrin," which, after some unavoidable delay, appeared in the *Lancet*, Sept. 26, 1914, p. 791. An abstract was given in THE JOURNAL, Oct. 24, 1914, p. 1508. In this paper the formula of the dextrin, which we isolated in a number of cases, was worked out and its probable relation to glycogen and starch shown. We were able to prove that the "pancreatic" reaction depends on the formation of an osazone by the pentose (xylose) split off from the dextrin by hydrolyzing with hydrochloric acid and that in the quantitative method the "iodin coefficient" of the urine is a measure of its content of dextrin. Our observations on the dextrin excretion are in agreement with those you quote, but we were also able to study the effect on the output of diseases of the pancreas, early glycosuria, and frank diabetes. One practical outcome of our observations has been to show that the appearance of sugar in the urine in diseases of the pancreas is preceded by a marked rise in the excretion of dextrin, which falls when glycosuria is established. It would therefore seem that determinations of the "iodin coefficient" are not only useful in the diagnosis of disease of the pancreas, but also afford a means of detecting and therefore treating diabetes in the preglycosuric stage with consequent better chance of success. In view of these and other results I think we can fairly claim to have established dextrinuria as a clinical entity, and it seems probable that the further investigations on which I am engaged will furnish information of value in relation to carbohydrate metabolism both in health and disease. In conclusion may I again state that neither the "pancreatic" reaction nor its modification, "the iodin coefficient" of the urine, has ever been claimed by me to be a specific test for disease of the pancreas? For several years I have stated that in my opinion it is merely an evidence of perverted carbohydrate metabolism which, when taken in conjunction with other evidence, is of assistance in the diagnosis of disease of the pancreas, since imperfect functioning of that organ is the most common cause of a metabolic failure in this direction.

P. J. CAMMIDGE, M.D., London, England.

Unauthorized Use of Name

To the Editor:—A display advertisement appeared in a Dubuque paper November 6 of the following verbiage:

"Mineral Water Mud Baths Cure Rheumatism at the Old Sanitarium, Prairie du Chien, Wisconsin. F. J. Antoine, Phy. Dr. Edward Evans, Sur."

My name was used without either my knowledge or consent. I have on file affidavits from the editor of the paper and the owner of the sanitarium saying that this advertisement was inserted without my knowledge or consent. You will confer a favor if you will insert this note in your Correspondence column. E. EVANS, M.D., La Crosse, Wis.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

QUESTIONS OF CORRECT LANGUAGE: "COCCI," "APPENDECTOMY" AND "SCOPOLAMIN"

To the Editor:—1. What is the proper pronunciation of words terminating in "cocci" and "coccic"? I sometimes hear the double "c" pronounced as if it were "k," sometimes as if it were "x" and sometimes as if it were "s."

2. What is the proper word to use to indicate the removal of the appendix, appendicectomy, appendiectomy or appendectomy?

3. What is the correct pronunciation of "scopolamin?" The latest dictionary puts the accent on the "a" but practically all physicians put it on the "o." I confess that euphony seems to be in favor of the pronunciation given by the physicians.

J. F. B., Columbus, Ohio.

ANSWER.—1. The double "c" in "cocci" and "coccic" should be given the ordinary English pronunciation, the first "c" hard like "k" and the second soft like "s.".

2. There seems no valid reason why the consideration of brevity should not prevail, giving the choice to "appendectomy." "Appendicectomy" is sometimes preferred on etymological grounds, but such considerations seem an unnecessary refinement since the word, being a hybrid, has no etymological right to exist.

3. Both euphony and derivation favor the accent on the second "o." Scopolamin does not belong to the class of amins; it is merely the alkaloid derived from scopola.

EXPOSURE AND IMMUNITY TO DIPHTHERIA

To the Editor:—1. Will you please inform me whether an adult having been in the same room with an individual who developed diphtheria the following day, but not in close contact, should be subjected to an immunizing dose of antitoxin, though she herself has had diphtheria?

2. Would your opinion be otherwise, if that individual were a teacher?

3. Is it not a fact that the majority of adults have a natural immunity to diphtheria?

4. Is it not a fact that the vast number of individuals who have once had diphtheria are immune to a second attack?

5. For how long does an immunizing dose render an individual passively immune?

A. R. HATCHER, M.D., Wellington, Kan.

ANSWER.—1. An adult exposed to diphtheria should be advised to receive an immunizing dose of antitoxin.

2. If the person is a teacher, she is bound to take every proper precaution.

3. The majority of adults have no marked immunity to diphtheria although they are less frequently attacked than children.

4. The immunity following an attack of diphtheria is very transient, lasting usually not more than three months.

5. An immunizing dose of antitoxin offers protection against the disease for a few weeks only.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Alabama: Montgomery, Jan. 5, 1915. Chairman, Dr. W. H. Sanders, Montgomery.

Alaska: Juneau, Jan. 5, 1915. Sec., Dr. H. C. DeVighne, Juneau.

Arizona: Phoenix, Jan. 5-6, 1915. Sec., Dr. John Wix Thomas, 200 Nat'l Bank of Ariz. Bldg., Phoenix.

California: Los Angeles, December 8. Sec., Dr. Charles B. Pinkham, 727 Butler Bldg., San Francisco.

Delaware: Dover and Wilmington, December 8-10. Sec., Dr. H. W. Briggs, 1026 Jackson St., Wilmington.

Illinois: Chicago, Jan. 13-15, 1915. Sec., Dr. C. St. Clair Drake, Springfield.

Indiana: Indianapolis, Jan. 12-14, 1915. Sec., Dr. W. T. Gott, State House, Indianapolis.

Kentucky: Louisville, December 16-18. Sec., Dr. A. T. McCormack, Bowling Green.

Maryland: Baltimore, December 8. Sec., Dr. J. McP. Scott, 137 W. Washington St., Hagerstown. Homeopathic, Baltimore, December 15-16. Sec., Dr. O. N. Duvall, 1817 N. Fulton, Baltimore.

Minnesota: Minneapolis, Jan. 5-8, 1915. Sec., Dr. Thomas McDavitt, 814 Lowry Bldg., St. Paul.

Missouri: St. Louis, December 14-16. Sec., Dr. J. A. B. Adcock, State House, Jefferson City.

New Hampshire: Concord, December 29-30. Regent, Mr. H. C. Morrison, Concord.

New Mexico: Santa Fe, Jan. 11, 1915. Sec., Dr. W. E. Kaser, E. Las Vegas.

North Dakota: Grand Forks, Jan. 5, 1915. Sec., Dr. G. M. Williamson, Grand Forks.

Ohio: Columbus, December 8-10. Sec., Dr. George H. Matson.

Oklahoma: Oklahoma City, Jan. 12-14, 1915. Sec., Dr. John W. Duke, Guthrie.

Pennsylvania: Philadelphia, December 1-3. Sec., Dr. N. C. Schaeffer, Harrisburg.

Rhode Island: Providence, Jan. 7, 1915. Sec., Dr. Gardner T. Swarts, State House, Providence

South Dakota: Pierre, Jan. 12, 1915. Sec., Dr. P. B. Jenkins, Waubay.

Utah: Salt Lake City, Jan. 4-5, 1915. Sec., Dr. G. F. Harding, 407 Templeton Bldg., Salt Lake City.

Vermont: Montpelier, Jan. 11-13, 1915. Sec., Dr. W. Scott Nay, Underhill.

Virginia: Richmond, December 15-18. Sec., Dr. J. N. Barney, Fredericksburg.

Washington: Walla Walla, Jan. 5, 1915. Sec., Dr. C. N. Suttner, Baker Bldg., Walla Walla.

Wisconsin: Madison, Jan. 12-14, 1915. Sec., Dr. John M. Beffel, 3200 Clybourn St., Milwaukee.

Connecticut July Report

Dr. Charles A. Tuttle, secretary of the State of Connecticut Medical Examining Board, reports the oral, practical and written examination held at New Haven, July 14-15, 1914. The total number of subjects examined in was 7; total number of questions asked, 70; percentage required to pass, 75. The total number of candidates examined was 20, of whom 17 passed and 3 failed. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Yale Medical School		(1911) 81; (1914)	87.9, 89.2
University of Louisville		(1903)	83.6
College of Physicians and Sur., Baltimore		(1913) 76.7; (1914)	75.1
University of Maryland		(1914)	84
Harvard University		(1901)	82.5
Tufts College Medical School		(1905) 76.2; (1913)	78.5
College of Phys. and Surgs. in the City of N. Y.		(1902) 89.5; (1903)	83.3.
Syracuse University		(1913)	76.7
Jefferson Medical College		(1914)	84.7
University of Pennsylvania		(1913)	83.7
University of Vermont		(1913) 75.4; (1914)	88.8
	FAILED		
University of Southern California		(1902)	61.8
Maryland Medical College		(1913)	65.2
University of Canatania, Italy		(1912)	64.9

Michigan Reciprocity Report

Dr. B. D. Harison, secretary of the Michigan State Board of Registration in Medicine, reports that 32 candidates were licensed through reciprocity from February to September, 1914. The following colleges were represented:

College	Year Grad.	Reciprocity with
University of Colorado	(1911)	Colorado
Bennett Medical College	(1912)	Illinois
College of Phys. and Surgs., Chicago	(1907)	Missouri
Hahnemann Medical Coll. and Hosp., Chicago	(1910)	Texas
Northwestern University	(1906)	Illinois
Rush Medical College	(1901) (1907) (1912)	Illinois
University of Illinois	(1912)	Illinois
University of Louisville	(1912)	Illinois
College of Phys. and Surgs., Baltimore	(1907)	Illinois
University of Maryland	(1912)	Maryland
Harvard University	(1908)	N. Carolina
University of Michigan, Homeo. Med. College	(1912)	Illinois
University of Minnesota	(1907)	Ohio
Missouri Medical College	(1908)	Minnesota
St. Louis University	(1895)	Missouri
Syracuse University	(1913)	Missouri
Cincinnati College of Med. and Surg.	(1906)	New York
Cleveland College of Phys. and Surgs.	(1879)	Indiana
Cleveland Homeo. Medical College	(1905)	Ohio
Eclectic Medical College, Cincinnati	(1898)	Ohio
Starling Medical College	(1913)	Ohio
Starling-Ohio Medical College	(1897); (1903)	Ohio
University of Wooster	(1912)	Ohio
Western Reserve University	(1887)	Ohio
Jefferson Medical College	(1912)	Ohio
Woman's Medical College of Pennsylvania	(1910)	Minnesota
University of Vermont	(1908)	Penna.
Marquette University	(1908)	Vermont
Victoria University, Ontario	(1913)	Wisconsin
	(1874)	Minnesota

Oklahoma Reciprocity Report

Dr. John W. Duke, secretary of the Oklahoma State Board of Medical Examiners, reports that sixteen candidates were licensed through reciprocity from April 14, to July 14, 1914.

College	Year Grad.	Reciprocity with
University of Arkansas	(1910)	Arkansas
College of Phys. and Surgs., Chicago	(1901)	Wisconsin
Indiana Medical College	(1906)	New Mexico
University of Michigan, Homeo. Med. College	(1908)	Arkansas
Boston University	(1891)	Arkansas
Ensworth Medical College	(1910)	Nebraska
Meharry Medical College	(1913, 3)	Tennessee
Memphis Hosp. Medical College	(1902) Texas; (1912)	Tennessee
Tennessee Medical College	(1908)	Tennessee
University of Nashville	(1908)	Tennessee
University of Tennessee	(1900)	N. Carolina
Baylor University	(1913)	Tennessee
Physio-Medical College of Texas	(1905)	Texas

Utah July Report

Dr. G. F. Harding, secretary of the Utah State Board of Medical Examiners, reports the written examination held at Salt Lake City, July 6-7, 1914. The total number of subjects examined in was 19; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 6, of whom 5 passed, including 1 osteopath, and 1 failed. Two candidates were licensed through reciprocity. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Rush Medical College		(1912)	84.8
University of Illinois		(1914)	86.9
Jefferson Medical College		(1913) 81.4; (1914)	85.2
	FAILED		
Meharry Medical College		(1914)	61

College	LICENSED THROUGH RECIPROCITY	Year Grad.	Reciprocity with
Missouri Medical College		(1883)	Wyoming
St. Louis College of Phys. and Surgs.		(1905)	Illinois

Vermont July Report

Dr. W. Scott Nay, secretary of the Vermont State Board of Medical Registration, reports the practical and written examination held at Burlington, July 14-16, 1914. The total number of subjects examined in was 13; total number of questions asked, 90; percentage required to pass, 75. The total number of candidates examined was 23, all of whom passed. One candidate was licensed through reciprocity. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Harvard University		(1905)	85.9
University of Vermont		(1912) 82.2; (1913) 81.7, 82.6; (1914)	76.4, 80.1, 81.5, 83.1, 84.1, 84.5, 84.5, 84.7, 85.2, 85.7, 85.7, 86.2, 86.8, 87, 87.2, 87.5, 87.5, 89, 93.6.

One candidate, a graduate of Dartmouth Medical School, 1913, was licensed through reciprocity with New Hampshire.

Book Notices

Frohse Anatomical Charts. Made under the supervision and assistance of the Institute of Anatomy, University of Berlin. Fourteen charts, with key to each chart. Price, $3.75 per chart. Chicago: A. J. Nystrom & Co., 1914.

This is an excellent series of fourteen wall charts illustrating human anatomy. More are promised. It consists so far of the following: skeleton and joints, 2; muscles, 2; viscera of thorax and abdomen, 4; peripheral nerves, 1; circulatory system, 1 (diagrammatic); ear, 1; eye, 1; median section through head and neck, 1; histology of skin, 1. Most are of life size, while those of the eye and ear and the median section through the head and neck are considerably enlarged. They are made from paintings which were planned and supervised by anatomists. They are admirably planned to show clearly and intelligibly the structures represented, and their scope includes the whole extent of those structures. They approach more closely to perfect anatomic accuracy than most representations of this kind. The painter, in making the main features stand out clearly and distinctly, has intentionally subordinated some details, as in the reduction of complexity in the arterial arcades of the mesentery. This is usually an advantage. The obturator nerve is represented as coming from the third and fourth lumbar nerves. Its usual origin from the second evidently did not exist in the subject from which the drawing was made. The left bronchus is represented as slightly larger than the right. On the whole the charts are unusually accurate, and excel in clearness, general scope and definiteness. In high schools and colleges they would be of very great interest and instructive value. Elementary physiology can hardly be intelligibly taught without some such help, and in laboratories of anatomy they are useful, especially on account of their wide scope, in correlating the structures in different regions of the body. Their admirable planning makes them a very effective means of instruction, and their artistic excellence and clearness will insure pleasure and satisfaction in their use.

Atlas und Lehrbuch wichtiger tierischer Parasiten und ihrer Uebertrager mit besonderer Berucksichtigung der Tropenpathologie. Von Dr. Med. et Phil. R. O. Neumann, o. ö. Professor der Hygiene und Direktor des hygienischen Instituts der Universitat Bonn und Dr. Med. Martin Mayer, Abteilungsvorsteher am Institut für Schiffs- und Tropenkrankheiten in Hamburg. Cloth. Price 40 marks. Pp. 580 with 1382 illustrations. Munich: J. F. Lehmann, 1914.

The fine series of medical atlases published by Lehmann has received a notable addition in the volume by Neumann and Mayer on animal parasites and their hosts. The colored figures number more than thirteen hundred and there are numerous and excellent diagrams and text figures. The beautifully colored lithographic plates are likely to remain for a long time the high water mark for work of this sort. On some of them more than twenty colors have been employed to bring out the features desired. Considerably more than half of the text is devoted to the protozoa, and the remainder to the higher animal parasites. The work does not pretend to be exhaustive and is more complete as respects the parasites of man than the parasites of domestic animals. So far as possible the writers have tried not to neglect questions of interest to the professional zoologist, but the main purpose of the work has been to further the interests of practical medicine. The book is indispensable to every active worker in the field of animal parasitology.

Nurses for Our Neighbors. By Alfred Worcester, A.M., M.D., Chief of Maternity Service, Waltham Hospital. Cloth. Price $1.25 net. Pp. 267. Boston: Houghton Mifflin Company, 1914.

Dr. Worcester calls nursing "our common problem." and evidently does not consider that it has been solved, or that it is even near solution, by the establishment of the modern hospital training schools for nurses. He laments the lack of personal service in nursing and says that the old-fashioned custom of neighbor nursing neighbor had much to commend it. Nursing, he states, "essentially is caring for the helpless, whatever may be the cause or form of the helplessness, whether it be that of infancy, or of old age, or of accident, or of sickness; but hospitals admit only certain forms of human helplessness, and generally only the rarer forms." Again: "Experience in hospital nursing is, of course, an indispensable part of the perfect nurse's training, but it is by no means the whole of it. In our hospital training schools nurses acquire wonderful technical skill, and an extensive knowledge of diseases. They become adepts in distributing themselves and in managing many patients. As assistants of the hospital physicians and surgeon they learn much of the science, but little of the art, of medical practice; whereas nurses need to know only little of the science, but all that is knowable of the art of helping the helpless." The author speaks highly of the training given in the German deaconess institutions, in which hospital nursing is considered only as one of the departments or specialties of nursing and the young women are trained in district visiting and general home nursing. Many of Dr. Worcester's criticisms are well founded. The impersonal attitude toward patients required of nurses in hospitals is out of place in home nursing and is resented, and rightly, by the family of the patient. Too often a nurse's attempts to institute a hospital regimen in a home create irritation and discomfort among the relatives which is bound to react on the patient. Frequently, also, the nurse appears callous instead of sympathetic, and this the family naturally resents. Superintendents of hospitals throughout the country would do well to read this book and apply some of the suggestions in the training of their pupil nurses.

Diseases of Children. By Various Authors. Edited by Archibald E. Garrod, D.M., M.A., F.R.C.P., Physician to St. Bartholomew's Hospital, London, Frederick E. Batten, M.D., M.A., F.R.C.P., Physician to the Hospital for Sick Children, London, and Hugh Thursfield, D.M., M.A., F.R.C.P., Physician to Out-Patients, Hospital for Sick Children, *London. Cloth. Price, $8.50 net. Pp. 1184, with 182 illustrations. New* York: Longmans Green & Co., 1913.

This is the work of twenty-two leading British pediatrists, and the aim of the editors is "a comprehensive and authoritative account of the present state of our knowledge of the diseases of children, set forth with a completeness which they believe has not hitherto been attempted in this country." With Thompson, Still, Cautley, Poynton, Hutchison and others among the collaborators, the book is an expression of the most authoritative teaching on diseases of children in Great Britain to-day. We have had occasion before in reviewing the books of Thompson, of Still and of Cautley, to emphasize the fact that the British authors are keen observers and good clinicians, and this book corroborates that opinion. True they have been quite untouched by the important work that has been done in Germany, especially on nutrition and its disturbances, but this very isolation and aloofness that has laid them bare to the charge of "provincialism" has a certain value in that it gives one a different point of view. Judged from this aspect, the present volume contains a wealth of useful information to both student and practitioner, and takes its place beside that of Cautley, as one of the two most comprehensive and complete British text-books on diseases of children.

Hygienisches Praktikum. *Ein Taschenbuch für* studierende Aerzte und Kreisarztkandidaten. Von Dr. Med. Paul Uhlenhuth, geh. reg. rat und ordentl. Professor der Hygiene an der Universitat Strassburg und Dr. Med. Hermann Dold, Privatdozent der Hygiene an der Universität Strassburg. Cloth. Price, $1.25. Pp. 272, with 90 illustrations. New York: Rebman Company, 1914.

This small book is intended as a laboratory supplement to lectures on hygiene. It covers such subjects as the hygiene of soil, water, food and drink, clothing, ventilation, light, etc. The object of the book is didactic and the methods are for the most part familiar. In connection with the microscopic examination of water it is not clear why organisms like Vorticella and Carchesium are figured while nothing is said about the algae and other micro-organisms sometimes responsible for offensive odors in water supplies. The bacterial examination of both water and milk is summarily dismissed. The discredited method of Eijkman for the detection of *Bacillus coli* is the only procedure mentioned. The methods given for the examination of meat, etc., are well described and up to date. One chapter deals with the determination of the amount of alcohol in beer and wine. Altogether the book cannot be said to be particularly well adapted for use in this country, although it doubtless serves a useful purpose in its place of origin.

Die Wasserstoffionen-Konzentration, Ihre Bedeutung für die Biologie und die Methoden Ihrer Messung. Von Professor Dr. Leonor Michaelis, Privatdozent an der Universität Berlin. Paper. Price, 8 marks. Pp. 210, with 41 illustrations. Berlin: Julius Springer, 1914.

This is the first of a projected series of monographs on subjects in the general field of plant and animal physiology, modeled after the "Monographs on Biochemistry" series which has been such an important addition to biologic literature. Michaelis' work on hydrogen-ion concentration is an excellent illustration of the possibilities of this method of publication, and serves to render accessible an authoritative discussion of one of the most important of the recent advances in the application of fundamental principles of physical chemistry to biologic processes. The recognition that "reaction" means the proportion of hydrogen and hydroxyl ions in a solution, and nothing else, has done much to clear up many misconceptions in physiology, especially concerning the chemical conditions existing within the blood and tissues, and has been the direct stimulant of much progress in biologic and clinical chemistry. Michaelis has been one of the chief contributors to this field of research, and presents his highly technical subject with simplicity and clearness. It is not necessary to recommend this work to chemists and biologists; but we may emphasize the importance of the subject of "reaction" to physicians who desire to be informed concerning the basal advances in medical sciences, and the opportunity which this book offers them to learn its principles and applications.

Ambidexterity and Mental Culture. By H. Macnaughton-Jones, M.D., M.Ch., Q.U.I. Cloth. Price 75 cents net. Pp. 102, with illustrations. New York: Rebman Company, 1914.

The author of this little book, written for the laity, being thoroughly convinced that right-handedness and left-sided speech are acquired characteristics, advocates the teaching of ambidexterity in the lower-grade schools. He believes that the alternating or synchronous action of the dual sided brain, left and right sides equally cooperating with the associated arm and hand, and equally educated in their functional powers and uses, must have its psychophysical influence on the individual. To him that nation whose people are ambidextrous has a great advantage over others. Whether his expectations will be realized or will remain mere hopes, the teaching of ambidexterity must result in great benefit to a person who may develop aphasia and right-sided hemiplegia later in life. The book is well written and permeated by the positiveness of conviction.

Kirkes' Handbook of Physiology. By Charles Wilson Greene, A.M., Ph.D., Professor of Physiology, University of Missouri. Eighth American Revision. Cloth. Price, $3 net. Pp. 790, with 509 illustrations. New York: William Wood & Co., 1914.

This new edition of Kirkes' standard work retains the general form and features of previous issues. New material has been added in accordance with recent advances in our knowledge of internal secretions, and the author notes that an attempt is made to use as a determining pedagogic horizon not only physiology but also clinical medicine and surgery. A book of this character which has stood the test of time and reflects the best thought and criticism of some of our best physiologists is a worthy addition to any medical bookshelf.

Manual of Medical Jurisprudence, Toxicology and Public Health. By W. G. Aitchison Robertson, M.D., D.Sc., F.R.C.P.E., Lecturer on Medical Jurisprudence, School of Medicine, Royal College of Surgeons, Edinburgh. Cloth. Price, $2.50. Pp. 560. New York: Macmillan Company, 1913.

The passage of new public health laws in England since 1908—the date of issue of the first edition—and the rapid advance in the methods of mechanical filtration of water as well as the increasing demand for the book has led the author to prepare a second edition revised to date. While medical jurisprudence, public health administration laws of evidence and rules of procedure in England differ widely from those in the United States, yet the high standing and wide experience of the author will entitle his book to consideration by any one interested in public health anywhere. The second edition is larger and better illustrated than the first.

Studien über die Fortpflanzung von Bakterien, Spirillen und Spirochäten. Von Dr. Med. E. Meirowsky. Paper. Price, 12 marks. Pp. 95, with 11 illustrations. Berlin: Julius Springer, 1914.

This work of Meirowsky was planned with the idea of proving that Schaudinn's idea of the protozoal character of the *Spirochaeta pallida* was correct. Using the method of vital staining in his studies on the tubercle, lepra, paratyphoid and other bacilli, as well as on various types of spirochetes, which he cultivated, he was led to conclusions almost diametrically opposed to the assumptions on which he based his work. A discussion of the methods employed and of the details of Meirowsky's work cannot be taken up. Suffice it to say that he shows that the *Spirocheta pallida* is to be classed among the lower forms of plant life, probably in the group of mycelial types, and is in no way related to the animal forms, such as the protozoa. The subject matter is clearly written, the studies outlined being presented in a convincing manner. Many photomicrographs and drawings add to the value of the work.

A Text-Book of Pathology for Students of Medicine. By J. George Adami, M.A., M.D., F.R.S., Strathcona Professor of Pathology, McGill University, and John McCrae, M.D., M.R.C.P., Lecturer in Pathology, McGill University. Second Edition. Cloth. Price, $5 net. Pp. 878, with 408 illustrations. Philadelphia: Lea & Febiger, 1914.

In this edition of this standard text there has been added a new chapter on "The More Important Infections and Their Prominent Features." Other changes include an endeavor to simplify the classification of tumors which is a praiseworthy effort; the relegation of the chapter on "Monstrosities and Abnormalities" to an appendix, which is a good idea, and the addition of ninety-one engravings and two colored plates, making a total of 395 of the former and thirteen of the latter.

Die Moderne Therapie der Gonorrhöe beim Manne. Ein Leitfaden für Studierende und Aerzte. Von Prof. Dr. Paul Asch. Paper. Price, 2.60 marks. Pp. 84, with 25 illustrations. Bonn: A. Marcus and E. Webers, 1914.

Dr. Asch discusses in this pamphlet a subject on which much has already been written of both a valuable and a useless nature. Dr. Asch, however, takes nothing for granted and, beginning on the threshold, writes in detail from his own experience. He seems particularly partial to the Janet irrigation treatment, and believes that when instituted early and cautiously this method will prevent serious complications. There is a section on vaccine therapy and one on endoscopy which reflect modern opinions.

Manual of Diseases of the Eye for Students and Practitioners. By Charles H. May, M.D., Instructor in Ophthalmology, College of Physicians and Surgeons, Medical Department, Columbia University, New York. Eighth Edition. Cloth. Price, $2. Pp. 440, with 377 illustrations. New York: William Wood & Co., 1914.

The seventh edition of May's popular book appeared in August, 1911, and was reprinted August, 1913. This, the eighth edition, brings the work up to date. Its popularity is attested by eight English editions, two German, two Italian, three French, two Dutch, two Japanese, four Spanish and four for the British Isles.

Der Tierversuch in Psychiatrie und Neurologie. Akademische Antrittsvorlesung. Von Dr. Gabriel Steiner, Privatdozent in Strassburg im Els. Paper. Price 80 pfennig. Pp. 22. Wiesbaden: J. F. Bergmann, 1914.

In this lecture the author passes in review the various experimental methods in psychiatry and neurology as applied to animal psychology. The brochure gains in interest as many of the animal experiments, for instance those of Otto Kalischer, Pawlow and von Bechterew, can be applied to the elucidation of problems in human physiology and psychiatry.

Medicolegal

Physician as Committee of Lunatic

(Lake et al. vs. Hope (Va.), 82 S. E. R. 738)

The Supreme Court of Appeals of Virginia affirms a decree in favor of the defendant, a physician, whom it was sought to remove as committee of one Lake, a lunatic, on the ground of alleged incompetency and lack of care, together with unwarranted extravagance in managing his ward's estate, which was worth over a quarter of a millon dollars. When the defendant entered on his duties as committee his ward was a very sick man, suffering from alcoholic neuritis and some cerebral disorder due to the same cause. He was a helpless invalid—could not sit up in bed, could not lift a glass of water to his mouth, could not even turn over in bed without assistance. Mentally he was always in a state of dread, thinking that something was happening to him. Such was his serious illness up to June, 1910, when the plaintiffs complained to the court that the defendant had failed or refused to call in the services of a specialist on the disease or diseases with which Mr. Lake was afflicted. However, in the spring of 1912, Mr. Lake had improved so much under the defendant's care that he could walk wherever he pleased, while his mental condition was practically that of a sane person who could act for himself in the management of his affairs, unless subjected to great and unnecessary mental strain. The court thinks that the evidence justified the appointment and retention of the defendant as committee, and the allowance to him of $100 a month for his services as physician and for his care of his ward's estate.

One of the items of expense complained of was the purchase and upkeep of an automobile and a boat for the use of Mr. Lake. It appeared that Mr. Lake, before his illness, owned and enjoyed an automobile, which was practically his only source of outside pleasure. This machine gave out and the defendant disposed of it in exchange for a new one, which exchange involved an outlay in money in the sum of $1,150, and the upkeep of it and the boat for the year cost $350.27, making a total of $1,500.27. A son of Mr. Lake acted as chauffeur. For a man of Mr. Lake's worth, incapable of any other recreation or pastime, this item of expense for his comfort and pleasure could not be reasonably considered extravagant or wasteful. Nor was the reasonable expense of a trip of several months, taken by Mr. Lake to a winter resort in Florida, objectionable.

Giving Treatments by Manipulation and Adjustment a Practicing of Medicine

(Harvey vs. State (Neb.), 148 N. W. R. 924)

The Supreme Court of Nebraska affirms a conviction of the defendant on eight counts, each of which contained this allegation: "Did then and there for remuneration unlawfully practice medicine by unlawfully treating and attempting to heal one (name of patient) for a bodily ailment through the manipulation and adjustment with the hands by the said Earle A. Harvey, of certain nerves, bones and tissues of the body of the said (name of patient) without first having issued to him, the said Earle A. Harvey, by the said State Board of Health of the state of Nebraska, a certificate or license to practice medicine." The court says that the information without doubt charged offenses under Sections 2717, 2723, and 2724 of the Revised Statutes of Nebraska of 1913.

To "operate on, profess to heal or prescribe for, or otherwise treat any physical or mental ailment of another," is "practicing medicine" by the express provision of Section 2724. It is unlawful in Nebraska to treat professionally and attempt to heal another by manipulation and adjustment of nerves, bones and tissues of the body without first obtaining a certificate or license from the State Board of Health, as provided in Articles 2 and 8, Chapter 27, of the Revised Statutes of 1913. Every such treatment constitutes a separate offense, although of the same individual and for the same physical or mental ailment, if such treatments are on different days and entirely independent of each other. So, although three counts in the information charged treatment of the same individual, but these treatments were on different days, and not dependent on each other, each was a violation of the law.

Much was said in the brief about the "liberty of the citizens to follow a profession" and to "pursue a lawful calling in a lawful manner." It was said that the state cannot "prohibit any calling or profession, save and except it be detrimental to the public welfare, public morals, public health, or a disturbance of the public peace. The state may not indirectly prohibit what it cannot prohibit directly, i. e., it may not prohibit the exercise and practice of chiropractic by refusing to provide an examination in the curriculum taught in the best schools and colleges of chiropractic—those branches deemed essential and put in operation by leading chiropractors—and compelling the chiropractor to procure a diploma from a medical college and take an examination in the curriculum of some of the sects of drug medication." But this court cannot amend the statutes, nor disregard the early decisions upholding and construing those statutes. The legislature has had ample opportunity to modify the laws, if they are considered harsh, unjust, or impolitic, and, not having done so, they must be enforced as the will of the public expressed through its lawmaking powers. All objections raised in the brief are answered by the plain provisions of the statute, as construed by early decisions of this court. The case of State vs. Buswell, 40 Neb. 158, involved what is called Christian Science healing, and was determined more than twenty years ago, upholding the statute. Little vs. State, 60 Neb. 749, involving the practice of osteopathy, was decided about fourteen years ago, and also upholds the statute.

Corporations Not Bound for Attendance on Injured Employees

(Journal & Tribune Co. vs. Lones (Tenn.), 169 S. W. R. 760)

The Supreme Court of Tennessee says that the company was sued by Dr. Lones for attendance on an employee who had his hand crushed while engaged in the line of duty in the company's pressroom. The injury was received at a late hour at night, when all officers, including the general manager and the assistant general manager, were absent from the publishing plant. The night editor was the highest agent of the company on duty, and, on being notified of the employee's condition, called Dr. Lones over the telephone to attend him. With regard to the first aid treatment, no question was made, the company having admitted responsibility therefor. The contest was over that portion of the physician's bill which represented subsequent visits to the injured man at a hospital to which he was removed, and for office treatment of him. Without determining just what the authority of the night editor was, in the absence of the general manager and his assistant, the court holds that a judgment rendered in favor of the physician, against the company, was properly reversed. It says that the rule is that even the general manager of a commercial corporation has no authority or power implied from his official position to commit his company to the payment of ordinary attendance (as contradistinguished from emergency attendance) by a physician or surgeon on an employee of the corporation, injured while in the line of duty.

Duty to Minimize Damages in Cases of Traumatic Neurasthenia

(Mickelson vs. Fischer et ux. (Wash.), 142 Pac. R. 1160)

The Supreme Court of Washington says that there is a duty, resting on every one who seeks to recover damages, to minimize the amount to be measured in dollars and cents. An allowance of damages in cases of traumatic neurasthenia touches the border of speculation at best, and it is manifestly unfair for one who seeks to recover of damages to put a defendant to the hazard of a further speculation by refusing the aids which science affords and which are available, or by postponing the time of treatment until after a trial and a verdict.

SOUTHERN MEDICAL ASSOCIATION

Eighth Annual meeting, held at Richmond, Va., Nov. 9-12, 1914

The President, Dr. Stuart McGuire, Richmond, in the Chair

Early Diagnosis of Pulmonary Tuberculosis

Dr. Charles H. Cocke, Asheville, N. C.: I cannot too strongly urge the value and necessity of careful history taking with the expectation of finding some contact infection. For the examination the patient must be stripped to the waist. No examination is complete without careful inspection of the throat with a laryngeal mirror. The Roentgen ray is also invaluable. Of the tuberculin tests, the subcutaneous is the test *par excellence* where there is no fever, a focal reaction bespeaking active disease, while a febrile reaction alone, unless obtained with the initial small dose, implies a high tuberculin sensitiveness and consequently almost certain probability of active tuberculosis.

Significance of the von Pirquet Test

Dr. Thompson Frazer, Asheville, N. C.: A positive cutaneous reaction is less frequent in children than it was once thought to be. The view usually held, that the reaction has significance only during the first two or three years of life, is not borne out by recent figures, and we should be suspicious of a reaction occurring up to the age of 10. Annual tests should be instituted in the effort to detect early infection. A negative reaction, negative on the repetition of the test, is valuable evidence of the absence of tuberculosis unless the child is suffering from advanced disease or acute disease, especially measles.

State Policy in the Management of Tuberculosis

Dr. W. S. Rankin, Raleigh, N. C.: The combination of cooperative sanatorium and correspondence school is of mutual advantage, the one developing the other. The combination gives the state an educational organization analogous to the ideal system of education in operation in Wisconsin. Our cooperative sanatorium in this system is the central university where about one-tenth of the consumptive population is treated and is taught what constitutes the right kind of treatment for consumption. These alumni, on returning home and seeing other cases not being properly treated, enable the sanatorium to improve the medical supervision of consumptives throughout the state. The correspondence school, an adjunct of the central university or sanatorium, puts the state government in almost personal touch with its entire tuberculous population.

The Federal Government and Our Tuberculosis Problem

Mr. G. M. Cooper, Clinton, N. C.: The national government should form a cabinet office of secretary of the public health, to rank with the army and agricultural departments; then let the national Public Health Service through each state board of health, invite any county that desires to cooperate with it in the work. Those who agree are to pay one-third of the expense incidental to maintenance of a whole-time, efficient health officer. The state board of health is to pay one-third, and the national government the remaining third. Under this plan the local county government would select the officer, subject to approval by the state and national health authorities. In this manner local self-government would continue to exist and the health officer would have the mail franking privileges, so that he could reach all classes of citizens. Open-air schools and tent colonies in each county would be established, and each county would be the center of a public health school in which preventive medicine would be taught.

President's Address: The Profit and Loss Account of Modern Medicine

Dr. Stuart McGuire, Richmond, Va.: The most distinct profit and loss in modern medicine has come about through changes in medical education, which have been accomplished largely through the effort of the American Medical Association, the Association of American Medical Colleges and the Carnegie Foundation for the Advancement of Teaching. It was recognized that each year a progressively increasing number of low-grade practitioners were being graduated by medical colleges and licensed by state governments. An investigation of the medical schools showed that many of them were poorly equipped, had scant clinical material and lacked sufficient funds to procure the necessary time of efficient teachers. To remedy this evil a deliberate and systematic movement was inaugurated to lessen the number and improve the quality of the men who were being added to the ranks of the profession. By moral suasion, by state legislation and by the combination of the better schools, the entrance requirements were advanced, the number and length of the teaching sessions were increased, the character and scope of the curricula were improved, and the minimum number and approximate pay of the full-time teachers were specified.

While the profit side of the specialist's account is large, still on the opposite page we find some items of loss. The high esteem in which the specialist is held, the pecuniary rewards which his services command and the advertising opportunities offered by his position have made him a victim of imitators and imposters, who deceive and defraud the public. Modern medicine is not responsible for the quack and charlatan, but it is responsible for the members of the regular profession found in every town and city who claim to be specialists, but who really do a general practice, and for others who, while they may limit their work to certain diseases, are not qualified as experts and have no more knowledge or experience in their diagnosis and treatment than the average general practitioner.

Pleural Effusions of Artificial Pneumothorax

Dr. Mary E. Lapham, Highlands, N. C.: Our five years' experience with artificial pneumothorax has led us to believe that the tendency to pleural effusions increases with the length of time the compression is maintained. We have had three types of pleural effusions, those developing without any clinical manifestations and no suggestions of any active process. The fluid may be first detected by the rise in pressure in the manometer, or by filling the needle, or be heard as a splashing sound by the patient. We call these myocardial effusions. A second class has developed in consequence of repeated traumatisms of the pleura as a result of an acute infection, such as an angina, or of chilling, or from other reasons commonly associated with ordinary pleurisies. We call these infectious pleurisies. A third class is due to tuberculous nodules and process in the pleural surfaces and these seem to have been favored by the separation of the pleural surfaces by the artificial pneumothorax.

DISCUSSION

Dr. W. S. Leathers, University, Miss.: There is no problem in public health that has more aspects than that of tuberculosis. There is no problem that has more difficulties associated with its solution. The best plan of attacking the tuberculosis problem is on a cooperative basis.

Dr. C. W. Stiles, Wilmington, N. C.: I take issue with the idea that the federal government is doing very little in regard to this problem. Every pound of meat that comes into a state has been inspected by the Department of Agriculture for tuberculosis. The federal government is carrying out certain restrictive measures in interstate commerce according to the law, which is no small contribution to the fight against tuberculosis. Unless the medical profession is willing to set an example by controlling its own members with regard to spitting, etc., it is foolish for us to go to the federal government and ask the state to change the Constitution of the United States in order to put local police power into the hands of the federal government.

Dr. Charles L. Minor, Asheville: The von Pirquet test has been misused. I have had cases of full-grown adults sent to me on account of a positive von Pirquet. We must not reach the conclusion that because every case reacts to this test, it is necessarily active tuberculosis. We must differentiate between latent and active tuberculosis; otherwise there will be great harm done.

Dr. Thompson Frazer, Asheville: The reason we fail to detect tuberculosis early is that we do not recognize it as a chronic disease with relapses.

Dr. W. L. Dunn, Asheville: A firm conviction on the part of the physician is necessary to impress a patient that he is ill with tuberculosis. The average physician is afraid to make an early diagnosis of tuberculosis and say so firmly to the patient, because he is afraid the patient will be unnecessarily treated or his activities will be interrupted.

Dr. E. C. Thrash, Atlanta: Many practitioners have made a diagnosis of tuberculosis from the fact that they obtained a reaction, and the result was that it would throw a well person into a panic and perhaps subject him to many inconveniences, possibly a trip away, while other persons subjected to the tests would have the disease. I have seen cases of far-advanced tuberculosis in which physicians said they did not have tuberculosis because the von Pirquet or tuberculin test proved negative.

Dr. William R. Kirk, Hendersonville, N. C.: We should not attach too much importance to the temperature curve alone, for very often we get the same curve in cases of malignant disease.

Dr. D. M. Malloy, Mobile: In New South Wales it is obligatory on every physician to report every case of tuberculosis. The law is stringent on this point, and carries with it a severe penalty in the way of a fine, and possibly imprisonment. The reporting of each case also carries with it a reward of five dollars.

(To be continued)

MEDICAL SOCIETY OF VIRGINIA

Annual Meeting held in Washington, D. C., Oct. 27-30, 1914

(Concluded from page 1978)

Trachoma

Dr. Taliaferro Clark, Washington, D. C.: Trachoma is protean in its manifestations. In the mucous membrane the lymphoid cells are stimulated and undergo enormous proliferation. There are pannus, granulations and the formation of scar tissue. The color depends on the vascularity. It requires an abrasion of the mucous membrane and moisture, and hence occurs most frequently in those living under bad hygienic surroundings. It constitutes a grave social and economic problem. From 1899 to 1901, 8.5 per thousand of all eye infections were due to this. Eighteen per cent. of all blindness in Russia is due to it. One thousand cases a year are treated in the Lemberg Hospital. In Posen and Silesia it is very prevalent. In Japan, of 400,000 recruits, 23 per cent. had trachoma. It is a world-wide disease. All seeking entrance to America are examined for trachoma. Twenty-two and seven-tenths per cent. of western Indians and 13 per cent. of Indians in Virginia have it. Only nineteen cases in negroes were found in a thousand examinations. The negro has been protected in the past only by his lack of opportunity to contract it.

Trachoma: Methods Adopted for Its Control in Eastern Kentucky

Dr. John McMullen, Washington, D. C.: In 4,000 eye examinations in Kentucky, 12 per cent. were found to have this disease. On some of the creeks, 75 per cent. of families had it. No class were exempt. Untreated it lasts a lifetime. The large family towel is a source of danger, and the lack of good light in the houses contributes. Prevention is synonymous with education. Teachers' institutes and church organizations have been enlisted. Parents and teachers had copies of popular pamphlets mailed to them. House-to-house visits were made and instruction given. District nurses are employed. Surgical treatment under a general anesthetic must be used for young children, and the period of treatment immediately following is very important. Three hospitals have been established, of fifteen beds each. Two of these are 20 miles from a railroad. They are kept scrupulously clean as an object lesson. Patients are given separate toilet articles. There is a dispensary connected with each. The first was opened in September, 1913, and the last in March, 1914. Over ten thousand cases have been treated. The average daily total cost of each hospital is $17.30. Gratifying and encouraging results have followed. Many who were formerly paupers have been made self-supporting. Trachoma should be a reportable disease in every state.

DISCUSSION

Dr. Joseph A. White, Richmond: Fortunately we are free from trachoma in the cities. I recently wrote to all the oculists in the state; very few had had any experience with this disease. In my experience of over thirty years in Richmond, I have seen not more than four or five cases. We are almost as much in the dark as to the treatment as to the cause. An effort to prevent corneal complications is important to prevent blindness.

Dr. C. R. Dufour, Washington, D. C.: Hospital work is the only way to eradicate this disease. It behooves the government to establish hospitals. Some in any given family seem to be immune. I think treatment should be made compulsory, as many accept it as a visitation of the Almighty and make no effort to get cured.

Dr. C. M. Miller, Richmond: I have seen but four cases in fourteen years, but we are confronted by this menace. The negro is not immune. The conditions under which he lives are horrible, and if it gets a start it will spread rapidly. The board of health should take a hand in this work.

Dr. W. E. Driver, Norfolk: At Hampton Normal School I had recorded 30 per cent. of Indians as having trachoma, but it was different from that which I have seen abroad; I think many of them are cases of tuberculosis. I have never seen a case in a negro, though in that school the whites and negroes are intimately associated.

Dr. Taliaferro Clark, Washington, D. C.: Tuberculosis is a destructive disease, while trachoma has new tissue building. In examining probably one million eyes, I have seen only one case of tuberculosis.

Dr. Joseph A. White, Richmond: I have encountered opposition from the oculists in the matter of public lectures on the eye, because they say they would be accused of advertising themselves. This method has the approval of the American Medical Association.

Dr. E. G. Williams, Richmond: We of the state health department have not been unmindful of this menace, but have tried to attack our problems at the point where the greatest need appears. The typhoid problem is the most pressing. We recently issued 50,000 copies of a bulletin on defective hygiene, and defective eyes are treated of in this.

Acidity, Alkalinity and Anesthesia

Dr. George W. Crile, Cleveland: Acidity of the blood is increased by muscular effort, emotional disturbances, surgical shock, infections, asphyxia, inhalation anesthetics, and excision of liver and kidneys. Ether, nitrous oxid and alcohol produce acidity. A certain degree of acidity is incompatible with life. At the point of death the blood is always acid. May not the acidity be the actual cause of death? I think it is. If epinephrin in sufficient quantity be injected the acidity is controlled. Acidosis results from starvation, diabetes and Bright's disease. The acidity of the blood is increased in two seconds after the beginning of nitrous oxid anesthesia. Acid inhibits the action of the cerebral cortex, but stimulates that of the medulla.

DISCUSSION

Dr. W. P. Carr, Washington, D. C.: The old physiologists said alkaline blood was necessary to carry off the carbon dioxid. This is a new and rather startling theory—acidity the cause of anesthesia. We have not yet grasped the importance of anoci impulses which reach the brain. The field opened up by this paper is enormous; we must have time to digest it. We can get this lesson at least, to make anesthesias as short and as light as possible, and use anoci methods.

9. **End-Results After Operation of Displacement of Uterus, Bladder and Rectum.**—The body of the uterus was replaced to its proper position in the pelvis by the abdominal route combined with some sort of vaginal repair in sixty-one cases. Of the 109 cases investigated by Wade, twenty-four were made by plication of the round and broad ligaments on the upper and anterior surface of the body of the uterus, according to the method of Coffey, combined with some form of repair of the cervix or of the vagina. The operation has been fairly satisfactory. In twenty-one cases the patient has had a restoration of the pelvic viscera to their proper position, and in twenty of the cases the patients felt an improvement after the operation. Five became pregnant subsequently; one miscarried at the twenty-fourth week of her pregnancy; four went to term and were delivered vaginally of living children.

The uterus was suspended by plication of the round and broad ligaments without the aid of vaginal surgery in three cases. The uterus was movable and in place in two cases, and in two cases the patients felt improved after the operation. One became pregnant subsequently, carried her pregnancy to the twelfth week, and then aborted. The uterus was suspended from the anterior abdominal wall with No. 2 chromic catgut combined with some form of vaginal repair in thirty-three cases. The uterus remained in its proper position in twenty-three cases. In twenty of the cases the patient felt some improvement after the operation; nine women became pregnant and eight were delivered of living babies; one died. The uterus was suspended from the anterior abdominal wall without repair of the vaginal tract in seven cases. One became pregnant; three felt better after the operation, and in five cases the uterus was in place and appeared to be movable.

Four cases of the Baldy or Webster method suspensions combined with a repair of the vaginal canal were investigated. Two of the patients showed the uterus movable and well placed, and two felt some improvement after the operation. None of the patients had become pregnant. The vaginal method of supporting the uterus, and with it the bladder and rectum combined with the suspension from above, has been satisfactory to the patient in forty-two of the sixty-one cases examined. The uterus has remained in position and has been movable in fifty of the cases; fourteen of the patients became pregnant; two aborted; ten had normal deliveries, and two were delivered by the aid of forceps. Thirty-six of the patients had had the uterus supported by repair of the posterior vaginal wall without suspension; twenty-eight of these women felt improved after the operation, and in thirty cases the uterus was movable and in good position. The prolapse of the rectum was relieved in ten of the cases examined. The bladder in fifteen cases, in which it was involved in the procidentia, was placed in its proper position in the pelvis in nine cases. Eight of these women became pregnant after the operation. The mobility of the uterus has never been interfered with when replacement was affected by support from below, and flexions of the body on the cervix have not resulted from the operation. One death occurred which was probably due to cardiac embolism.

15. **Technic of Intestinal Anastomosis.**—Gray substitutes a continuous locking suture for the interrupted sutures used by Maunsell. The suture begins at the approximated mesenteric borders in the form of a circular stitch enclosing *all* four mesenteric leaves, the tail of the suture being left sufficiently long to tie to the other end on its return. The suture is then carried rapidly around the aperture of anastomosis, the stitches, penetrating 1/8 to 1/16 of an inch below the free borders and placed about that distance apart, locked at each thrust by passing the needle under the loop before drawing it home, which should be done under considerable tension. The final tie leaves a single knot that of necessity lies within the bowel.

22 *Prothrombin. W. H. Howell, Baltimore.
23 *Coagulation of Lymph. W. H. Howell, Baltimore.

21. **Faradic Stimuli.**—Erlanger and Garrey report in detail the results of a study of the shocks yielded by induction coils of the types commonly used in the laboratory, with a view to the determination of their configuration *in relation* to their efficiency as stimuli under conditions commonly obtaining in physiologic investigations. The deficiencies of the string galvanometer as an indicator of currents of such short duration as induction shocks are discussed, and a rheotome method (the gap method) of making it possible to conveniently determine qualitatively and quantitatively the configuration of shocks with the string galvanometer, is described. A platinum contact key for make shocks is also described.

22. **Prothrombin.**—Howell found prothrombin may be precipitated by acetone from oxalated blood-plasma and be obtained in solution free from the other fibrin factors, with the possible exception of traces of antithrombin. The prothrombin is converted to active thrombin in the presence of calcium salts. No third factor seems to be necessary for

this activating process. The activating property of calcium salts is exhibited to a much less extent by strontium salts, and very feebly by magnesium salts. The prothrombin in salt-free or salt-poor solutions is weakened but not destroyed by heating to 60 C. Aqueous extracts of the blood-platelets show the presence of both prothrombin and thromboplastin. Prothrombin (probably some thromboplastin also) is contained in the plasma of circulating blood. In shed blood disintegration of the platelets furnishes an additional supply of prothrombin and thromboplastin.

23. **Coagulation of Lymph.**—The lymph used by Howell in his experiments was obtained from dogs by placing a cannula, vaselined along its inner surface, into the thoracic duct. The animals were anesthetized with morphin and ether. The flow from the cannula was variable, but in fed animals with a milky lymph was quite abundant, averaging about 0.5 c.c. to a minute. He found that the coagulation-time of lymph varies greatly. In well-fed animals with much chyle-fat in the lymph coagulation is slower than in the clear lymph from fasting animals, but the addition of thromboplastic material (tissue-extract or kephalin solutions) causes the lymph to clot promptly and firmly. Lymph plasma contains antithrombin in the same concentration as in blood-plasma. When freed from corpuscles by long centrifugalization the lymph plasma clots with great slowness, owing to a relative excess of antithrombin. Addition of kephalin solution to such plasmas causes prompt clotting. The thromboplastin in solution in lymph-plasma is less in amount than in the blood-plasma. In shed lymph a new supply of thromboplastin is furnished by the lymphocytes, but more slowly than in the case of the blood in which the additional thromboplastin is derived from the unstable platelets. Prothrombin is present in solution in the circulating lymph. Its activation to thrombin by calcium is retarded or prevented by the relative excess of antithrombin.

24. **Pulse-Flow in Brachial Artery.**—In febrile patients showing palpable types of the dicrotic pulse, Hewlett found that the brachial flow curves show characteristic changes. These consist in a marked backflow in the brachial artery just after the entrance of the primary pulse-wave and in an inflow and outflow with the dicrotic wave. In the form of pulse described as monocrotic there is also a marked outflow just after the primary pulse-wave, but no marked dicrotic wave follows. This type of pulse is closely related to the typical dicrotic pulse. The primary wave in each has a pointed character. Other things being equal, the pointed character of the pulse in the arm is increased by vasoconstriction of the arm arterioles and is diminished by their relaxation. In many, if not in all cases, factors outside of the arm play a part in the production of the jointed pulse. Among such possible factors are (1) a brief systolic output from the heart and (2) a dilatation of certain vascular areas outside of the arm, the most important being the splanchnic vessels.

25. **Non-Protein Nitrogen and Urea of Blood in Health and Disease.**—Analyses of the blood for total non-protein nitrogen and urea nitrogen were made by Tileston and Comfort by the methods of Folin in five healthy adults and 142 hospital cases. In the fasting healthy adult the total non-protein nitrogen varied between 22.9 and 25 mg. per 100 c.c. of blood, and the urea nitrogen between 12 and 14 mg. The effect of a full meal with meat in the case of the healthy adult was a rise of total non-protein nitrogen averaging 4.7 mg., and of urea, averaging 2.5 mg. In both chronic interstitial and chronic diffuse nephritis the cases without symptoms of uremia showed normal or moderately elevated values; the uremic cases, with one possible exception, showed a great increase in both nitrogen and urea. The excretion of phenolsulphonephthalein was roughly proportionate to the degree of retention; the cases with 100 mg. or over of total nitrogen all showed 5 per cent. or less phenolsulphonephthalein excretion. Many cases, however, with a considerable impairment of phenolsulphonephthalein excretion showed no signs of retention, and a moderate amount of retention of waste nitrogen often occurred with no impairment of the elimination of phthalein. The proportion of urea nitrogen to the total non-protein nitrogen in disease varied from 32 to 85 per cent. Where the nitrogen was normal the urea usually was about one-half the total nitrogen; where it was elevated, the urea usually but by no means always constituted about 70 per cent. of the whole. No reason could be found for these variations. The determination of the total non-protein nitrogen alone is therefore more valuable than that of the urea alone. The determination of the total non-protein nitrogen is a great aid in the prognosis of chronic nephritis. Patients showing over 100 mg., with one exception, did not live more than thirty-five days.

The results of blood analysis furnish the best guide as to the diet to be given in nephritis; cases with a considerable retention require a restriction of the protein, and by this means a return to normal figures may be brought about, if the azotemia is not too pronounced. In cases of outspoken uremia, however, no marked reduction of the azotemia has resulted from a protein-poor diet. Nephritis with a normal amount of non-protein nitrogen does not call for any marked decrease of protein in the diet. Many other lesions were investigated in this connection. For the results obtained in these cases the original article should be consulted.

26. **Epidemic of Sore Throat Traced to Milk of Cows.**—There were 348 cases of sore throat in the series investigated by Capps and Davis, most of them complicated by enlargement of the cervical glands and many by a marked exudate. Cultures from a number of throats showed a hemolytic streptococcus. In a canvass of 913 households, in 60 per cent. of the cases of sore throats, milk or cream from Dairy X was used, although this dairy supplied only 17.5 per cent. of the households. The morbidity rate in one institution supplied by Dairy X was 40 per cent.; in four other institutions supplied by other dairies it averaged 1.7 per cent. Among 1,000 customers of Dairy X, 215, or 21.5 per cent., developed sore throat, whereas among 6,416 customers of other dairies, 133, or 2.1 per cent., developed the disease. As a result of a systematic inspection of 416 cows on thirty-eight dairy farms, eleven cows with garget were found. Bacteriologic examinations revealed hemolytic streptococci in the milk of two of these diseased cows. The milk of both of these cows was distributed by Dairy X. As Dairy X did not pasteurize the cream at all and the milk very inadequately, Capps and Davis conclude that the streptococci originating in the bovine mastitis were probably responsible for the epidemic. Because of the extensive distribution of ice cream, manufactured from the Dairy X cream, they suspect that ice cream played an important rôle as a carrier in this epidemic.

28. **Methods of Prophylactic Immunization Against Typhoid.**—The history of the development of artificial immunization against the typhoid bacillus in animals and human beings is reviewed by Gay and Claypole, and some of the many preparations of the typhoid bacillus used for this purpose are discussed. Particular attention is drawn to the reputed advantages of living sensitized typhoid vaccine (Besredka) as opposed to other types of vaccine. The many vaccines that are still being advocated indicate that the best vaccine

has not yet been found and that the best method of proving which is the best vaccine has not been determined. Sensitized cultures of the typhoid bacillus, whether whole or as sediment, produce little or no reaction in human beings with the possible exception of those who have previously suffered from typhoid or have been immunized. By comparing their results with those of certain other observers, the authors conclude that a considerable degree of reaction, both local and general, is avoided by the use of these sensitized cultures, which possess the further advantage, so far as their experimental work can determine, of producing a more durable type of immunity.

The authors recommend vaccination at short intervals (two days) in human beings, which is rendered quite possible with the mild vaccine they employ, and is evidenced from animal experimentation, as giving rise to less toxic effect and to fully as durable an immunity as vaccination at longer intervals. This type of vaccination has the further advantage of completing the prophylactic treatment of three injections within a week. They further believe that a polyvalent vaccine derived from strains of the typhoid bacillus isolated in the vicinity of patients who are to be treated is advantageous, judging largely from the work of other observers. A further advantage in the use of sensitized cultures is that a polyvalent vaccine, no matter how recently the strains may have been isolated, is also almost entirely free from untoward effect. They recommend for prophylactic immunization against typhoid, three injections of the sediment of a dried, ground, sensitized culture of several local strains of the typhoid bacillus mixed together, given at two-day intervals and in a dosage of $\frac{3}{32}$ mg. of the original dried culture, which corresponds, as has been determined, to a dosage of approximately 750 million living typhoid bacilli.

30. **Experimental Pathology of Stomach.**—Hamburger and Friedman found that moderate pyloric stenosis in dogs (ligature around pylorus tied loosely) causes little or no change in stomach motility, acidity or size. Marked obstruction (ligature tied sufficiently tight to produce marked peristalsis and anemia of the pylorus) causes motor insufficiency, continuous secretion (hyperacidity) and hypertrophy and dilatation of the stomach. Complete occlusion (ligature or silver nitrate injection causing secondary occluding edema) results in inanition, vomiting, convulsions (gastric tetany) and death of the animal in from forty-eight to 120 hours. The pyloric ligature (stenosis) results in a motor insufficiency with food retention which in turn sets up a continuous secretion with the constant presence of free hydrochloric acid. Pyloric obstruction with resulting motor insufficiency and continuous secretion are probably the most important factors in the production of chronic experimental ulcer. While the foregoing results concern experimental chronic ulcer, the authors conclude that it is more than likely that primary partial pyloric stenosis (from whatever cause) with secondary motor insufficiency and continuous secretion are largely responsible for the progression and delayed healing of chronic ulcer in man.

31. **Hexamethylenamin as Urinary Antiseptic.**—The urines from 91 patients were examined by Levy and Strauss. The greater number of these patients received 7 gm. of hexamethylenamin three times a day. Most of the urines were examined twice and some of them as many as six times. About 250 urines were examined. The 91 cases may be divided as follows: surgical 42, medical 32, genito-urinary 17. The urines of all of the 91 patients gave a test for formaldehyd varying from 1:20,000 to 1:5,000. The urines from 72 patients showed the presence of formaldehyd in the strength of 1:10,000. The colon bacillus was the most common invader of the urinary tract, occurring in 64 per cent. of the cases. To be of [illegible] therapeutic value, the hexamethylenamin or its derivative would have to be excreted in a concentration strong enough to be either inhibitory or bactericidal. The action of a 10 per cent. solution of hexamethylenamin was tried on various organisms.

The authors found that formaldehyd to be of value must be liberated in strengths varying from 1:15,000 to 1:5,000, depending on the organism the growth of which is to be inhibited. To be of bactericidal value it must be liberated in strengths from 1:5,000 to 1:1,000, also depending on the organism. For the destruction or inhibition of growth of organisms other than the typhoid bacillus a high acidity is necessary. This high acidity in combination with the formaldehyd may produce injury to the kidney tissue. Hexamethylenamin, therefore, appears most efficacious as a prophylactic during the course of typhoid for the prevention of a pyelitis or cystitis.

32. **Blood-Platelets and Tuberculosis.**—Blood-platelets are consistently increased in the tuberculosis of man and guinea-pigs. At an altitude of 6,000 feet, blood-platelets are increased in the circulating blood of man and guinea-pigs. Blood-platelets would appear either to contain or to supply opsonin. Blood-platelets added to a lethal dose of tubercle bacilli appear to modify the course of infection or to prevent it. The addition of serum to a mixture of blood-platelets and tubercle bacilli appears to interfere with this modification.

33. **Pulmonary Physical Signs and Roentgen-Ray Findings in Healthy Adults.**—A careful physical examination of the chest of fifty healthy adults by Baetjer showed the pulmonary physical signs to be practically normal in eleven, definitely though not markedly altered in thirty, more obviously altered in seven and greatly changed in two. That the changes in the physical signs are the expression of corresponding changes in the lungs is borne out by the results of the Roentgen-ray examinations made by Baetjer. Forty-six of the series had roentgenograms taken and in only six were the apices found to be normal. The results of the physical and Roentgen-ray examinations, although agreeing in a large proportion of the cases, still not infrequently are at variance. In twenty-two of the forty-six cases the agreement is complete. The disagreement in the remaining twenty-four cases is as follows:

In six instances the physical examination shows practically normal conditions, whereas the Roentgen-ray examination shows slight apical clouding. In eighteen instances the physical examination indicates a definite lesion at one apex, whereas the Roentgen-ray examination shows clouding at both apices. In four instances the physical examination indicates a slight lesion at one apex whereas the Roentgen-ray examination shows clouding at the opposite apex. In all four instances the changes in the physical signs were very slight. In two instances the physical examination indicates slight abnormalities at one apex whereas the Roentgen-ray examination shows both apices to be clear. In four instances the physical signs indicate a lesion at both apices, whereas Roentgen-ray examination reveals clouding at only one apex.

45 Intra-Abdominal Hemorrhage Complicating Normal Pregnancy. F. G. Balch and R. M. Green, Boston.

42. **Chlorophyll Test of Gastric Motility.**—In answer to the question whether the test is better than older methods of

testing gastric motility, White says that it is simpler than most; makes little demand on the appetite, and is very easy on the stomach. It is readily used in patients who are vomiting, or who are on a very simple light diet, in which a big meal is uncomfortable or impossible. The sources of error are few and probably unimportant and no considerable disturbance of motility escapes detection. It is an easy method of following results of treatment of gastric stasis. It is probably not superior in accuracy and not likely to replace the best of the older tests, but it is simpler and easier for both physician, and patients in a large group of cases and gives an extra "string to our bow."

44. **Use of Radium in Cancer and Allied Conditions.**—The best, apparently curative, results from radium therapy, Ordway states, are obtained in certain types of skin and other localized forms of cancer. In myelogenous and lymphatic leukemia the blood picture becomes almost normal, the spleen is reduced markedly in size and certain symptoms may be relieved without toxemia resulting. In many cases of true cancer which have advanced beyond the operable stage, or those recurring after operation, improvement from radium therapy may follow not only subjectively but in the local condition. This improvement may include relief from discharge, hemorrhage and pain; cleansing or healing of ulceration; diminution in size or disappearance of the growth. Such cases, however, are rarely cured. Even large growths sometimes disappear under the influence of radium but metastasis or spreading of the growth to other parts is not prevented, or the patient may succumb to the rapid disintegration of the original growth. Newer methods may improve these results of radium therapy; at present its proved value is limited, but occasionally cases beyond these well recognized limits are distinctly benefited.

54 Use of Exercise in Treatment of Tuberculosis. C. W. Mills, Loomis, N. Y.

51. **Ten Years Work at Gaylord Sanatorium.**—With the Gaylord Farm Sanatorium, the state home for tuberculosis, with the New Haven Hospital equipment, the New Haven Dispensary for tuberculosis, the house to house work for the Visiting Nurses' Association, the New Haven Employees' Relief Association, with the Day and Night Camps, the out-of-door and open-window schools, the Improved Housing Association, the Waterbury Antituberculosis League, the Meriden Tuberculosis Relief Association, and the State Board of Health, Fisher says, New Haven County has one of the best equipments for fighting tuberculosis in the United States or in the world. Outside of the county the state tuberculosis commission has its other homes and there are several local antituberculosis organizations, including a summer camp for girls at Litchfield, maintained by the Reverend Mr. Chapman. Active work is being done in Hartford, South Manchester, New Britain, Norwalk, Stamford and Bridgeport. Outside of the state of Connecticut the influence of Gaylord Farm has been not inconsiderable. It has been the inspiration for the formation of other antituberculosis associations and sanatoria, hospitals and dispensaries. It has supplied what many believed to be the best type or model for combining the activity of the state and of the general public in the hygiene of tuberculosis. In states in which sanatoria have been instituted by the government without private cooperation, they have been more or less blighted by politics. In cases in which, on the other hand, antituberculosis work has been undertaken without state aid, it has been crippled for lack of funds. A happy combination of state aid and private initiative seems to be the true solution. Aside from supplying a model for organization and administration, the association has lent specific aid to the antituberculosis work outside of the state.

The National Association has helped to establish over 1,000 state and local antituberculosis societies; helped to secure over 550 hospitals and sanatoriums, with more than 35,000 beds for patients; 400 dispensaries, with over 1,000 physicians in attendance; over 200 open air schools and fresh air classes for anemic and tuberculous children; and more than 3,000 nurses engaged in tuberculosis work. It has helped to get laws passed in forty-five states and local ordinances in over 200 cities, dealing with the treatment and the prevention of tuberculosis. Active field campaigns of education in forty states and territories have been carried on and no less than 100,000,000 pamphlets on tuberculosis have been distributed in the last ten years. The National Association has expended in ten years only $200,000 but has stimulated national, state and local agencies to expend about $100,000,000. It is reported that out of $20,000,000, which were expended last year in the fight against tuberculosis, over two-thirds, or nearly $14,000,000, were expended out of public funds. These include expenditures by federal, state, county or municipal governments. The best way of registering statistically the general effect of the antituberculosis movement is in the reduction of the death-rate. It is found, according to the census reports, that tuberculosis in all its forms in the states in which registration has been kept since 1900, has declined from 181 per 100,000 in 1901 to 150 per 100,000 in 1911. This is a decline of 17 per cent. in ten years, the decline being 12 per cent. for males and 23 per cent. for females.

64. **Association of Follicular Tonsillitis with Acute Gastric Fever.**—The frequent occurrence of gastric fever, Fischer says, demands a careful inspection of the tonsils and when such tonsils show evidence of hypertrophy they should be treated as diseased tissue which may be a focus for future malignant infections. Loss of appetite, or rather a refusal to eat, will be noted; all symptoms pointing to a gastric derangement will be present, and still the predominating

symptom will be the patches or follicles on the tonsils, causing pain on swallowing. Fischer emphasizes that too much importance cannot be placed on the necessity for throat inspection in every child that refuses to eat.

The treatment he advocates is as follows: An alkaline laxative such as a 3 to 5 grain dose of compound jalap powder should be given and repeated every three hours until a thorough evacuation have been produced. During this eliminative treatment water should be given liberally but no food. Locally, for the throat tincture of iodin diluted with an equal quantity of water should be applied once with the aid of a cotton swab. After the bowels have been thoroughly cleaned, chicken soup or milk from which the cream has been skimmed or weak tea may be permitted. For the after-treatment 1 or 2 drops, depending on the age, of tincture of nux vomica may be given before meals.

81. **Intraspinous Medication.**—Following the intraspinous introduction of 5 c.c. normal saline solution rather rapidly, a gradual increase in the pressure was noted by Berghausen there being no sudden variations; as when tricresol is added in 0.5 per cent. concentration, to the normal saline solution, there was a sudden rise then a fall, and a secondary rise. The same result was obtained when the tricresol was added to distilled water in the same concentration. The needle was introduced into the spine, a few drops of fluid were allowed to flow, the needle was withdrawn, then introduced into another interspace in the lower lumbar spine, and so on. There were distinct variations in pressure, now a rise and then a fall. Apparently, then, the simple procedure of spinal puncture is likely to be followed by variations in the peripheral blood-pressure.

Berghausen is convinced from a study of this and other experiments that sudden variations in peripheral blood-pressure are likely to follow the simple procedure of spinal puncture and the subsequent injection of simple solutions; that the addition of tricresol in 0.5 per cent. concentration has no distinct deleterious effect beyond the slight toxic effect which all phenol derivatives possess in this concentration and which makes them useful as antiseptics; that serious damage can be done to the cord through the insertion of the needle too high into the spine, the immediate damage being probably due to hemorrhage, chiefly subdural.

In accordance with these findings, Berghausen controls all intraspinous injections by taking the peripheral blood-pressure after the method of Sophian. Particularly in epidemic meningitis, sudden variations in the peripheral blood-pressure are noticeable. In fact, it not infrequently becomes necessary again to withdraw the serum (using the gravity method only), owing to the fact that the blood-pressure had fallen distinctly, at times 30 to 50 mm. below the original pressure. In Berghausen's experience, sudden respiratory changes follow only when the blood-pressure has suffered a marked change, usually a drop. It is a safe rule never to withdraw the needle until the blood-pressure at the close of the injection has about reached that which was registered at the outset. The gravity method is of distinct value in attaining this end, since it affords a ready means of withdrawing the serum and fluid.

83. **New Method of Hastening Repair After Fracture.**—Kauffer makes use of homogeneously granulated bone incorporated with petrolatum, injected into and between the fractured ends of bone, to encourage repair in fractures, especially in cases of delayed union. A piece of bone (a fresh specimen obtained from the morgue) is dried and ground up to a powder, mixed with petrolatum to a consistence of bismuth paste, sterilized by placing in a large bottle, which is placed up to the neck in water and boiled for two hours. Keep in a cool place. When required, it should be warmed and well mixed by shaking, taken up into a 4 or 8 c.c. syringe, using a long needle, with a bore about gauge 20.

After the fracture has been extended and approximated, it is located by digital examination and Roentgen ray; the needle is introduced through the skin and fascia to the seat of fracture, the rough edges of which are readily appreciated. The needle is then passed as deeply as possible between the fractured ends. The contents of the syringe are injected as the needle is slowly withdrawn to the surface of the bone, when injecting must stop and the needle be removed. This procedure may be repeated into the fracture at several angles, if necessary, thus infiltrating the entire mass between the fractured ends with petrolatum and bone cells, which act as a focus for osteogenesis. The powdered bone and petrolatum are also recommended wherever bone is required. Kauffer says that the powdered bone invites calcareous deposits and encourages a metaplasia of the adjacent tissue cells.

91. **Trachoma Treated with Bacillus Lactis Bulgaricus.**—Hudgel's method of treatment was as follows: One per cent. atropin once daily; hot fomentations three times daily; twice during the course of treatment he turned the lids back and scarified them thoroughly with a small bistoury. They bled freely. Twice daily he reduced to powder a tablet of the Bulgarian bacillus and dusted it on each everted lid. No astringents or other remedies were used. The improvement was marked from the start. The copious lacrimation was checked at once and the patient said his eyes felt much cooler and easier. The ulcers healed and the pannus gradually disappeared. The improvement of vision kept pace with the amelioration of the various phases of the disease. When discharged two weeks after commencing treatment vision with correction was 15/20. The eyes were clear and felt free from irritation.

10. **Anoci-Association.**—Pannett experimented on cats and rabbits and found that afferent impulses set up by incision of the abdominal wall in the linea alba can be prevented from reaching the nerve centers by local infiltration with novocain, as recommended by Crile. When the incision is not in the middle line, these impulses can be blocked only by anesthetizing the nerve trunks as well as employing local infiltration to render the nerve-endings insensitive. This procedure may necessitate the waiting of some minutes between the injection of the anesthetic and the severance of each layer. If perineural injections are employed, 1 per cent. novocain must be used. Afferent impulses resulting from manipulation of the viscera have in general a more pronounced effect on the vasomotor center than those resulting from the opening of the abdomen and the retraction of the edges of the wound. To bring about a condition of anociassociation of the nerve centers, it is as essential to cut off impulses ascending from the viscera as it is to block those coming from the abdominal wall. Afferent impulses set up by manipulation of the stomach, intestine and the attachments of these viscera, may be blocked by local anesthetization of these attachments. The tone of the abdominal muscles is increased by the manipulation of the viscera or by dragging on the parietal peritoneum. This reflex rigidity can be eliminated by locally anesthetizing the abdominal wall and by blocking impulses from the viscera.

15. **Etiology of Appendicitis.**—Appendicitis, gastric and duodenal ulcer, and probably certain forms of mucous colitis, Lansdown and Williamson hold originate from the action of some noxious agent on these structures. These diverse conditions are essentially associated with one another as the result of an underlying common cause; and sepsis and chronic ulceration are either secondary features or sequela of such disorder. There are in the substances of the mucous membrane of the intestinal tract certain small round-celled aggregates more or less distinct from the lymphoid follicles. These structures are associated with a particularly simple epithelium. They occur in areas of concentration in the stomach, duodenum, appendix and upper rectum. The distribution within the stomach and duodenum occupies what might be called the ulcer area. They appear to suffer some general enlargement or destruction in appendicitis, gastric and duodenal ulcer, and certain form of dyspepsia. Sepsis as a secondary process can be engrafted on such changes in the appendix, and it is to be considered as a sequela. Similarly, chronic gastric and duodenal ulcer is the outcome of some secondary irritation acting on these diseased foci. There is a pathologic link between appendicitis, certain dyspepsias and chronic gastric ulcer.

16. **Treatment of Arthritic Deformities.**—Jones emphasizes that deformities are preventable if a surgeon be acquainted with the natural course of disease. In view of ankylosis the joint should be allowed to become fixed in the position of greatest usefulness as regards function. In children most deformities can be corrected by manipulation and osteotomies and exsection of bone are very rarely required. The reduction of deformity in a septic or tuberculous joint during the existence of disease can be safely undertaken if it be immediately followed by fixation. In sound fibrous ankylosis of the hip an osteotomy should be preferred for the correction of adduction, as some recurrence of deformity would follow reduction by manipulation.

The site of osteotomy will depend on the nature of the ankylosis and on the extent of the deformity. Transtrochanteric osteotomy gives the most accurate mechanical result. It should be practiced in all cases of bony fixation in which the femoral neck is not absorbed and in which there is no marked pathologic dislocation. In cases in which the destruction of the head and neck have occurred and the femur lies close on the pelvis, a wedge should be removed from the neighborhood of the trochanter. In cases of fibrous ankylosis in the process of becoming sound, a subtrochanteric osteotomy is indicated to prevent strain on fibrous bands. All osteotomies require subcutaneous division of the adductors. Subtrochanteric osteotomy is contra-indicated in cases in which flexion is extreme.

Arthroplasty of the hip-joint in any of its many forms, Jones says, may be looked on as a valuable and successful procedure. The character of the intervening substance whether bone, free or pedunculated fascial flap, fat, or muscle, is not so important as a good technic and a sound judgment. It should not be performed on children nor in the presence of active disease. It should be reserved for adult life, and has proved more successful after recovered septic than after tuberculous disease, and in case of septic disease it should be postponed for one or more years until the periarticular structures have become more normal.

The results of arthroplasty of the knee are not too encouraging. In bony ankylosis of the femur and tibia the results are distinctly discouraging. In those instances in which the ankylosis is fibrous, with perhaps bony fixation of the patella, results are often good. In such conditions, however, Jones states, mobility may often be secured without operation. In painful and progressive deformities, such as in osteo-arthritis of the hip, many procedures may be expected to give relief by preventing the friction of tender joint surfaces.

17. **Mechanical Considerations of Human Foot.**—Rowell's main conclusion is that for the ordinary inactive life of the drawing-room, office and shop, high-heeled boots and shoes may be advantageous in giving to the feet a pleasant, braced-up feeling, quite different from that enjoyed or suffered by those who slither about in heelless slippers.

18. **Soldiers' Feet and Footgear.**—When a man's feet are sore and inflamed, but not blistered, Webb-Johnson says, it is advisable for him regularly to do one of the following: (a) Rub the feet night and morning with spirit, to which may be added 1 to 2 per cent. of salicylic acid. (b) Paint the tender parts once or twice a day with either a saturated solution of picric acid or a solution of chromic acid (2 to 3 grains to the ounce). (c) After drying the feet, sprinkle with a powder composed of talc and salicylic acid (salicylic acid 2 grains, talc 1 ounce). (d) Soak the feet in a bucket of cold water to which potassium permanganate, salt, alum, tannic acid, or saltpeter has been added.

Men who complain of excessive sweating of the feet should soak them daily in a solution of formalin and water (1 to 800), dry them, and dust them with zinc oxid or some other powder. Tender feet may be well greased with zinc or boracic ointment, or the soles of the feet may be soaped. When a man's feet are normally fatigued at the end of a long march, after he has washed and dried them, he will find great relief if he lies down and raises the feet by resting them against some firm object.

If, in spite of all these precautions, a blister forms, the fluid should be evacuated aseptically and the surplus skin, liable to cause pressure cleared away. An antiseptic ointment should then be applied and the blister covered with stockingette plaster. As, after the heel, the most common situation for a blister is the plantar aspects of the fourth and fifth toes, it is in this case advisable to use animal wool round and under the toes to counteract the flexion which causes the pressure on these parts.

23. **Significance of Blood-Pressure Readings in Man.**—In doing blood-pressure estimations MacWilliams and Melvin find it desirable to determine the diastolic index while the armlet pressure is being raised; in some (rare) cases in which arm compression leads to a marked rise of blood-pressure, the diastolic reading taken with a rising armlet pressure may differ from that obtained during the lowering of the armlet pressure (after determining the systolic index) by as much as 20 mm. This is especially the case when simultaneous estimations are made in the two arms. But a decided effect is sometimes observed when only one arm is tested. Comparison of the diastolic values with rising and falling armlet pressures may thus give important indications of the liability of the arterial pressure to vary in an abnormal way, when a large artery is closed, as in the process of systolic estimation.

As regards the impressions derived from digital examination of the pulse, they have found the impression gained as to (a) the tension in the vessel within the beats (diastolic pressure), and (b) the extent of the change at systole (pulse pressure) to be specially fallacious in some cases—apparently more deceptive than the impression as to the compressibility of the pulse (systolic pressure). An enormous pulse pressure (for example, 120 mm. in a case of aortic regurgitation) may be present, as shown by measurement of the systolic and diastolic pressures, when the finger fails to give any adequate conception of such a pressure wave along the artery. And the measured diastolic pressure may be very high when the impression given by digital examination is that it is rather low.

35. **Pruritus Ani.**—In every case of pruritus ani, in which no satisfactory causative factor can be found by external examination or examination of the anal canal with the sphincteroscope, Norbury urges that a thorough investigation of the rectum and pelvic colon by means of the sigmoidoscope should be carried out. In this way hidden lesions may be discovered, and treatment established on a sound basis. For instance, pruritus may be the result of irritating discharges from simple or malignant growths in the bowel, from certain forms of colitis or proctitis; granular proctitis or the hypertrophic catarrhal variety. Norbury has had several cases of pruritus ani associated with a large granular patch of mucous membrane, and situated in the lower part of the rectum proper; treatment by rectal injections with sulphate of zinc and local applications of silver nitrate has given considerable relief.

41. **Rhinosporidium Kinealyi.**—Tirumurti shows by a recital of cases that the name Rhinosporidium is a misnomer, because the parasite is found in other situations than the nose, though the nasal mucous membrane is its favorite site. The occurrence of the sporozoon in the conjunctival and nasal mucous membrane is explained by direct inoculation through infected clothing, handkerchiefs, or the hands. The spores are discharged in the nasal secretion, which is rather

profuse in patients who suffer from this parasitic polypus in the nose, and who are subject to chronic nasal catarrh and profuse bleedings from the nose.

The growth of the parasite being usually one of long duration, the source of the infection is forgotten and a history of close contact is not easily elicited. The preponderance of the parasitic cysts in large numbers, mainly in the epithelial and subepithelial tissues, is also suggestive of this mode of conveyance of the disease by infected nasal secretion. The occurrence of the parasite in the penis in a man who was otherwise healthy and showed perfectly normal appearances of the conjunctiva and nasal mucous membrane, is very suggestive of direct inoculation through sexual congress.

Tirumurti suggests that rhinosporidial polypi do occur in the mucous membrane of the mouth, anus and vagina, but are overlooked, microscopic examination not being conducted in every case. The growths have a great tendency to recur, though after their removal the bases are cauterized. Thorough cauterization may prevent a recurrence. The clinical features of the growths are characteristic, though the characters are modified according to the site of their occurrence. The recurrence and innumerable number of cysts of the parasite, in different stages of development in a small fragment of the tissue affected, are in favor of the sporozoon undergoing its complete cycle of development in the human body without the intervention of an intermediary host.

43 *Excretion of Arsenic in Urine after Subcutaneous or Intravenous Injection of Salvarsan. K. Irokawa.

43. **Excretion of Arsenic in Urine After Injection of Salvarsan.**—Irokawa injected salvarsan either subcutaneously or intravenously in eight cases of syphilis, two cases of tabes dorsalis and one case of epilepsy and examined the daily excretion of arsenic in the urine for from three to thirty-nine days. He found that from 40 to 90 per cent. of the arsenic injected is excreted in the urine. When salvarsan is injected subcutaneously, it remains at the site of the injection unabsorbed and one can detect the arsenic in the urine, even when it does not cause any inflammation, after three weeks. The excretion of arsenic after intravenous injection is quite slow; and one can prove the presence of arsenic in the urine even after three weeks. In a relatively large number of the cases 10 per cent. of the arsenic is excreted during the first day, but the greater part is excreted in the course of the first week.

46 Jagged Wounds from Rebounding Bullets. (Des blessures par balles de ricochet.) Rochard.

45. **Surgery in the Base Hospitals.**—Témoin declares that his experience with 800 wounded has confirmed anew the necessity for refraining from operative mutilations. . . . "One can never reiterate enough *combien il faut être sobre de mutilations chirurgicales.*" "Notwithstanding the vast destructive lesion, notwithstanding the distressing appearance of the shattered tissues, notwithstanding the way in which the bones are fractured at several points and project from the wound, even notwithstanding the appeals of the wounded who plead for amputation to put an end to their suffering, conservative surgery, thanks to the means now at our disposal, yields extremely satisfactory results, so satisfactory that we should consistently refuse to amputate when the wounded are first brought in. Almost all fractures, no matter what the complications, heal perfectly. All that is necessary is to disinfect the wound and immobilize the limb as early as possible." Prompt and definite immobilization was followed by rapid and complete healing in his thirty-seven compound fractures of the humerus, thirty-five of the leg and twenty-seven of the thigh. Only one man required amputation and he had developed tetanus. A wide gap is left in the plaster apparatus to permit dressing the wound. He warns against attempting to explore the wound with fingers or instruments; a simple flat dressing, not attempting to bring the lips of the wound together, is the entire surgical task for the first few days. If wounds of the skull do not prove immediately fatal, they seem to heal with less disturbance than with trauma of the skull under other conditions. In the latter case they are generally the result of a fall on the head and the whole brain suffers more from the concussion.

Certain complications of modern artillery wounds are opening up a new chapter of pathology and surgical practice. The infectious complications develop so rapidly that any intervention is futile. Another complication is the serious secondary hemorrhage which comes on the fourth to the tenth day, when the wound seems to be healing favorably. Then the wounded region, limb, axilla or neck begins to pain and swell, and the temperature runs up. The aspect of the region suggests an abscess but instead of pus when it is incised, a large mass of ill-smelling clots is evacuated with putrefied clots in the depths. If not incised, gangrene is almost certain to develop. If nothing is done but clear out the clots, the immediate relief is great, but during the day or night fulminating hemorrhage comes on, and many have died from this secondary hemorrhage. The only way to avoid it is to realize that when the region is thus uniformly swollen, with agonizing pain and total inability to use the limb—which is never observed with ordinary abscess or phlegmon—some vessel is bleeding into the tissues, and an emergency operation is called for to ligate this vessel above and below the lesion. He lost the first patient from gangrene but the other seventeen were saved by ligating the carotid or femoral arteries, the axillary and brachial or the latter alone or the popliteal or anterior tibial. The wounded should be carefully sifted so that those whose wounds require institutional care should not be taken where such is not available. The sifting out of the wounded is thus a very important task. It can be done on the trains during the transportation, and the case-card should be of a different color for those requiring special skill or equipment.

56 Operative Treatment of Bladder Tumors. (Blasentumoren.) O. Hildebrand.

47. **Operations on the Stomach.**—Küttner states that 10 per cent. of all his surgical work at Breslau in the last seven years has been on the stomach. In the total of 1,100 stomach cases two-thirds were malignant and only 20 per cent. of these were operable. The proportion of operable cases was lowest in patients who came from private practice. One woman was in the hospital for a year on account of multiple cysts in the upper third of the femur, first on one side and then on the other. Necropsy revealed that the cysts were metastases from a gastric cancer which had been entirely unsuspected, although the woman had been under super-

vision for all that time. Malignant disease of the stomach apart from the pylorus causes achylia and mechanical conditions like those artificially induced by a gastro-enterostomy. This explains why cancer of this kind can exist so long without attracting attention. In 15 per cent. of his cancer cases there had been preceding stomach trouble, but whether gastritis, ulcer or achylia is not known. In one case both a cancer and an ulcer were found in the stomach, and in another five or more separate cancers. The operable cases generally had a longer history of disturbances than the inoperable ones. Roentgenoscopy was usually disappointing except when it disclosed inoperable conditions. The Gluczinski method of differentiation proved reliable. The later the pain develops after eating, the nearer the pylorus the lesion is found.

He resects only when cancer cannot be excluded with absolute certainty; that is to say, he does resection in every case of tumor-forming callous ulcer, as he is convinced that this is in reality of cancerous nature. The fear of transformation of other forms of gastric ulcer into cancer is not borne out by his experience; there were only two in which cancer developed later, in his 120 cases, and the ulcer was of the callous type. After-hemorrhage from an ulcer treated by gastro-enterostomy was responsible for the death of one patient, and also for that of another treated by resection. Perforation did not occur after gastro-enterostomy in any instance, and the ultimate outcome was a complete cure of all disturbances in 65 per cent. and essential improvement in 20 per cent. The ultimate outcome was also surprisingly good after a gastro-enterostomy done for sagging of the stomach, thus kinking the pylorus. The results when the pylorus was excluded were no better than with simple gastro-enterostomy alone.

51. **Transplantation of the Thyroid.**—This report of Kocher's experimental and clinical experience fills nearly one hundred pages. He has only good results to report from the twenty-one patients treated by this means alone. The lessons learned from this material in regard to the conditions for success are presented in detail, as well as for the technic.

53. **Exophthalmic Goiter and the Thymus.**—Kocher states that no instance of Basedow's disease is yet known in which at necropsy or operation the thyroid was found free from hyperplasia, but the thymus is often apparently normal. In nearly 50 per cent. of all cases of Basedow's disease a tendency to tardy hyperplasia or tardy involution of the thymus is evident. Hyperplasia of the thymus is more frequent in younger Basedow patients. No special histologic findings were discovered in the thymus with Basedow's disease at necropsy of fourteen cases; six had died under operative treatment and eight from the Basedow alone. When there is hyperplasia of the thymus, the patient might be prepared for an operation on the thyroid by a course of thymus extract and Roentgen exposures of the thymus, just before the operation on the thyroid.

54. **Antethoracal Restoration of the Esophagus.**—Von Hacker gives a profusely illustrated description of the technic with which he provided a girl of 12 with a functionally capable esophagus after the natural passage had been impassibly corroded by swallowing a tablespoonful of lye. It had been given her by her mother, who took a similar dose and died of the injury. The operation was done at several sittings, the entire procedure requiring about six months. The plan was to take a segment of the transverse colon and implant it in the lesser curvature of the stomach and bring the other end up under the skin nearly to the clavicle. The esophagus was severed above the stenosis and the proximal stump brought out through a transverse incision in the neck and worked down under the skin and sutured to the upper end of the colon segment. The illustrations show a healthy girl with scarcely any trace of her injury except a linear scar from the umbilicus to the neck.

57. **Tetanus.**—Weintraud says that the number of cases of tetanus among the wounded makes it imperative to recognize the first symptoms of it, which only too often the patient—"in his touching patience and ignorance of the dangers to which he is exposed"—regards as too trivial to mention. They may include dizziness, heavy sweats, slight difficulty in urination, a feeling of tightness in the muscles of the jaws or back of the neck, or brief spasms of the muscles of the chest or of the diaphragm. The latter are liable to be mistaken for pleurisy pains. The technic and dosage for serotherapy should be mastered beforehand and no one should be misled into assuming that antitetanus serum can be given like diphtheria antitoxin. Its efficacy lies in prophylaxis and the immunity conferred is transient.

When tetanus is once installed, Weintraud continues, little can be hoped from serum treatment, but we have an important symptomatic aid in Meltzer and Auer's magnesium sulphate treatment. He has been so much impressed with the value of this measure that he urges all medical societies to devote a meeting to it, exhibiting the classic guinea-pig experiment, injecting subcutaneously 7 c.c. per kilogram of weight of a 25 per cent. solution. All the voluntary and involuntary movements of the body are entirely arrested. Unless artificial respiration is applied the guinea-pig dies without any signs of pain or suffocation. The animal lies relaxed without a single manifestation of life except for the heart-beat and blood-pressure which with small doses persist almost normal. Artificial respiration restores normal conditions and the animal seems none the worse for his experience. The animal can be restored also by injecting 5 or 10 c.c. of a 5 per cent. solution of calcium chlorid slowly into a vein in the ear. In twenty seconds the animal begins to breathe deeper, rouses in a minute, and in a short time cannot be distinguished from its normal mates.

This exhibition convinces all of the extreme value of magnesium sulphate in tetanus, but it warns also of its dangers. Too small a dose does no good, and too large arrests the breathing. The individual susceptibility differs also. In the three cases of recovery at Wiesbaden the patients had all been given magnesium sulphate. After a single injection the rigid muscles relaxed, breathing became deeper and freer, cyanosis and sweating subsided, and the patient sank into refreshing slumber. If he is wakened anew by pains and spasms, these can be relieved again by the sulphate. Individual tentative experience must be the guide to dosage. To date, he says, fifty cases of tetanus have been given this treatment, and the mortality of 35 per cent. is being constantly lowered. Kocher lost only one of his six patients, and this one succumbed to sinus thrombosis. The intraspinal technic is scarcely applicable outside of institutional supervision. No one physician can carry it through alone; in one case in his service eight intraspinal injections were given during the week, thus arresting the paroxysms each time as they returned, until finally the tendency was conquered. The general practitioner must content himself with subcutaneous injection. Brilliant results have been attained with it, but even this requires the most devoted supervision, keeping the patient under this long, deep, lasting anesthesia and yet not letting it be so deep that the relaxation paralyzes vital functions. The danger of total arrest of the respiration confronts one constantly. The aspect, the tint, are no criteria; the breathing must be watched for the slightest tendency to paralysis of the respiratory muscles.

With intraspinal injection the spinal canal can be washed out when the effect is too intense, but with subcutaneous injection no relief is possible in this way, but the drug can be more or less completely neutralized by the antagonistic action of 5 c.c. of a 5 per cent. solution of calcium chlorid, injected intramuscularly, repeated several times at need. Artificial respiration, however, is the main reliance and may suffice alone, especially if preceded by an injection of 1 mg. physostigmin salicylate. If these fail, intratracheal insufflation is within the reach of every one. If there is no oxygen tank available, air can be pumped in with an ordinary bellows. If skilled in intubation technic, tracheotomy can be avoided.

In conclusion, he reiterates that the sulphate does not menace the heart directly, but the heart may need camphor from the exhaustion following the spasms. He does not seem to have had any personal experience with the subcutaneous technic, but cites others to show that the dose should be at least 15 or 20 c.c. of a 20 per cent. solution or 12 or 16 c.c. of a 25 per cent. solution for an adult. Parker injected 28 c.c. of a 25 per cent. solution at a time. Mielke thus cured a girl of nearly 6 with doses of 3 gm. in a 20 per cent. solution three times in twenty-four hours, to a total of twenty-four injections, using up 61 gm. of the drug. Of course, the smallest effectual dose should be used. The relief from the sulphate is so great that the patients pay no heed to the local pain of the injection, but this can be reduced by giving a little morphin.

Unger describes a method of treatment which he has applied in one case with apparent success. Antitetanus serum was injected into the ulnar or radial artery through a ureter catheter, pushed in until the tip reached the arch of the aorta. The serum thus pumped in passed at once to the brain through the carotid arteries and into the spinal cord through the descending aorta. He has often introduced ureter catheters in this way far up into veins and arteries. Heddaeus has recently reported a somewhat similar intra-arterial technic, injecting the antitetanus serum directly into the internal carotid artery. He had applied it in six cases of tetanus with gratifying results.

60. **Cholera.**—Lichtwitz confesses that he has had no experience with cholera, but theoretically is convinced that great benefit might be derived from epinephrin administered intravenously by the drip method, taking two or three hours to inject half a liter of the epinephrin-salt solution, as for peritonitic shock. This replenishes the epinephrin in the circulation as fast as it is eliminated. When this technic is impracticable, the next best is to inject occasionally 100 c.c. of the solution as slowly as possible. Another point which he emphasizes is that when bolus alba or charcoal is used it must not be forgotten that this will absorb and nullify the action of drugs given soon before or with it. It is also liable to absorb and nullify the digestive ferments, and thus impair the appetite.

66. **First-Aid for Injuries of the Eyes.**—Von Hess says that he has seen a number of cases in which the optic nerve had been cut by a bullet while the eye itself had scarcely been injured. When the eye is injured the first thing is to determine whether it is perforated or not. If the tension of the eyeball is found reduced, on cautious palpation, there is certainly perforation, but this cannot be excluded even if the tension is found normal; the hole may close up behind a minute splinter in the eyeball. A hemorrhage in the anterior chamber is generally absorbed in a week or so, but when the blood penetrates into the vitreous body it is never entirely absorbed. A copper scrap is peculiarly dangerous in the eye, as it rapidly induces aseptic suppuration; when a copper splinter is supposed to be in the eye, the man should be rushed to a specialist with extra speed. Iron or steel scraps, on the other hand, do not threaten special danger for a few days. It may be weeks or months before siderosis bulbi develops. Lead should be got out early.

He says that sympathetic ophthalmia develops only when a chronic iridocyclitis follows on a perforating injury of one eye. The signs of this are discoloration of the iris, a precipitate with tenderness and photophobia and congestion in the ciliary region—evident a week or two after the injury and especially when the ciliary region was involved in it. With these findings the patient had better be advised to have his eye enucleated, as this alone will protect certainly against sympathetic ophthalmia. If the eye suppurates after the perforating injury (hypopyon, panophthalmia), sympathetic ophthalmia need not be feared. A small superficial foreign body can be removed with a small scalpel at need, holding it flat; it does no harm to slice off some of the epithelium around, as this regenerates in a day or so under a well-fitting bandage. At the front, foreign bodies which are not superficial should be left unmolested. No occlusive dressing should be applied to the eye when there is much conjunctival secretion. The eye should not be bandaged except when there is a loss of substance in the cornea or prolapse of the iris. Even after opening a stye, the eye should not be bandaged. Mucous or purulent conjunctival secretion can be combated in emergencies by everting the lids and dabbing them with a 1 or 2 per cent. solution of silver nitrate once or twice a day. This must never be instilled into the eye.

68. **Gastrogenous Diarrhea.**—Jonas tabulates the findings in five cases of achylia, in five of hyperacidity and in five of extreme gastroptosis. Comparison of these groups shows that the behavior of the pylorus in abnormal conditions is what determines whether diarrhea or constipation shall prevail. When it is unduly permeable, as with achylia, subacidity, and in some cases of hyperacidity and atony, there is a predisposition to diarrhea, while the reverse tendency prevails with defective motor functioning of the stomach and bowel and unduly long closure of the pylorus.

73. **Pressure on the Brain with Certain Eye Diseases.**—Heine says that if we regard the cornea as a protruding part of the brain, then the meninges are practically continuous with the uveal tract. The first sign of irritation of the meninges is increased secretion of cerebrospinal fluid, and he found this pronounced in over three-fourths of 63 cases of uveitis. The coincidence occurred too regularly for it to be regarded as casual. It testified that with inflammation in the choroid, the iris or the ciliary body, the meninges share in the irritation. In 16 of the 30 cases of iritis, it was of tuberculous origin; syphilitic in 5; gonorrheal in 1; all three in 1; in another case there was sinusitis and in another diffuse atheroma. In the 33 cases of choroiditis, 13 were of tuberculous and 10 of syphilitic origin. Twenty-four of the patients in each group were men. In the 30 cases of iritis one eye only was involved in 23, but only in 8 of the 23 choroiditis cases.

74. **Technic for Serodiagnosis.**—Fetzer and Nippe call attention to the value of the malachite green test in revealing by a change in color the slightest admixture of blood. With the aid of this test it is possible to avoid serious error from the presence of blood in doing the Abderhalden test.

75. **Coagulation Test for Syphilis.**—Fränkel and Thiele confirm the diagnostic importance of the inhibition or delay in coagulation as a sign of syphilis. In seventy cases tested the findings paralleled those of the Wassermann test. The coagulating influence seems to proceed from the ether-soluble fraction of the thrombokinase or cytozyme. Syphilitic serum destroys this, and thus prevents coagulation. (Compare with Abstract 75, page 1241.)

77. **Open Treatment of Suppurating Wounds.**—Schede asks what is the use of trying to keep profusely suppurating wounds bandaged. The body is striving to throw off infected secretions, and why cannot we help it in this task instead of our futile efforts to staunch the copious discharge. Oftener than not, the dressings directly hinder instead of promoting Nature's efforts, while the changing of the dressings threatens the environment. An illustration shows the two plaster casts and iron strip frame between, with which he secured the rapid healing of severe shrapnel injuries of the leg. Almost at once the secretions lost their fetid odor and purulent character, the fever subsided, and necrotic tissue was cast off by healthy granulations. When the secretions are too thick to drip, he steams the wound under a cover and thus obtains a "moist dressing" without the drawbacks of shutting off the air and retention of secretions. In other cases superheated air answers the purpose better. If the suppurating focus is on the top of the leg, he provides for drainage by a counter incision in the depths of the lesion. The great advantage of this plaster-cast open method, he reiterates, is that each lesion can be treated as it needs, open or covered, moist or dry, aseptic or antiseptic, and it can be bandaged at any time when the healing has progressed to render this desirable. The plaster and the iron cost far less than the constantly to be renewed dressings with such a lesion, while the patient is spared all the pain and discomfort of change of dressings.

October 22, No. 43, pp. 1379-1398

87 *Dentistry Protheses for the Wounded. (Der Zahnarzt im Kriege.) M. Kraus.

86. **Lumbar Puncture in Treatment of Chorea.**—Passini remarks that the latest text-books have changed chorea from the "diseases of the nervous system" chapter to the chapter on "infectious diseases." Recent research has apparently demonstrated that the choreic movements are the result of irritation of the cerebral tracts passing from the red nucleus to the dentate nucleus. He examined the spinal fluid in a number of cases of chorea developing secondary to acute articular rheumatism; some of the children had signs of having passed through endocarditis, but all were free from fever and the chorea had been under way for several weeks unmodified by any measures. Lumbar puncture in five exceptionally severe cases showed that the fluid was under high pressure, from 30 to 40 c.c. spurting as the patient reclined and still more escaping as the child sat up. The fluid was clear and apparently sterile. In three of these five cases the chorea promptly and permanently subsided after the lumbar puncture. In the two other cases the chorea was of a year's standing and no benefit was derived. The lumbar puncture was repeated later and showed normal pressure, but the choreic movements persisted unmodified. Evidently the part of the nervous system involved had suffered beyond possible recuperation from the overpressure or from toxic elements in the cerebrospinal fluid. Lumbar puncture before irreparable lesions are installed seems to have a direct curative action.

87. **Dentistry Protheses in Military Surgery.**—Kraus concludes his remarks on the necessity for trained assistance in this line for the wounded, by urging that the results are incomparably better when the prothesis is applied early. Healing can then proceed along normal lines and there will be nothing to undo later, while old disfiguring deformity in hard callus is difficult to correct.

88 *Treatment of Ascites. II. (Zur Beseitigung des Ascites.) J. Kumaris.

89 *Phenol-Camphor in Local Treatment of Phlegmons in Joint and Tendon Sheaths. (Hochprozentige Karbol-Kampferspiritusinjektionen gegen Phlegmonen in Gelenken und Sehnenscheiden.) G. W. Schiele.

88. **Ascites.**—Kumaris reports here three cases in which the technic he advocates has been applied with perfect success. He excises a patch of the parietal peritoneum and thus induces adhesions. (Described in The Journal, Jan. 31, 1914, p. 421.) One patient died twenty-two days later from erysipelas, and there was no fluid found in the abdomen. The cure was complete when the patient was seen a month later in another case, and also during the six months to date in the third case. This patient was a man of 55. The incision was carried down to the mesentery of the ascending colon, up to the cremaster hepatis and toward the colon on the left. A tongue-shaped flap was then cut in the peritoneum and turned back over the fundus of the bladder, and a wisp of omentum was drawn down into the exposed space of Retzius. A stretch of the prevertebral peritoneum was also loosened up. By the end of forty-eight hours the edema in the ankles had disappeared, the abdomen was free from pain, the walls soft and edematous. There was slight oozing from the upper part of the wound for a few days, and then a subcutaneous infiltration required puncture the fourth and sixth weeks, after which approximately normal conditions were restored and have been permanent to date.

89. **Phenol-Camphor for Phlegmons.**—Schiele writes to corroborate the great benefit from injection of a mixture of 30 parts liquefied phenol with 50 parts triturated camphor in 8 parts alcohol. He has never witnessed anything suggesting intoxication with this treatment, while his invariable success with it has convinced him that practically always it will abort incipient phlegmonous processes in cavities, especially in large and small joints and tendon sheaths, and the method deserves a trial in gunshot wounds and tardy abscesses. Among the typical cases described is that of a young woman with a phlegmon in the sheath of the flexor tendon of a finger. He filled the cavity with the mixture and the tendon could be exercised without pain, and the three incisions healed without impairment of function. The injection was repeated daily, the tendon swimming in the oily fluid. In another case 5 gm. of the fluid was injected into the knee joint every second day after evacuation at first of 150 gm. of purulent secretion. The phlegmon had followed an external injury. The pain and fever disappeared promptly, and by the third day the man of 55 was walking, using the knee.

91 *Production of Antibodies in Leukemia. (Fähigkeit von Leukämikern Antikörper zu erzeugen.) H. Rotky.

91. Antibody Production in Leukemia.—Rotky reports a series of experiments on eight patients with tuberculosis or multiple sclerosis and on two leukemics, testing them all for agglutinating properties in the blood. The findings confirmed in every respect Moreschi's recent statement that the blood in leukemia has no agglutinating power. Rotky accepts this as indicating incapacity for production of antibodies, and suggests that this explains the lack of resisting power in leukemia to otherwise harmless infections.

106. Progressive Pernicious Anemia.—Mikhailoff reports excellent results from spleen extract in the treatment of pernicious anemia. He produced pernicious anemia in 18 rabbits by injecting phenylhydrazin for four to five days. Ten were left without treatment and 8 of these succumbed by the third to the fifth day. The other 8 rabbits were treated with spleen extract, and in all the blood-picture returned almost to normal. Encouraged by these results, Mikhailoff used this treatment in a very severe case of pernicious anemia in a man of 26, who had had every other known treatment applied without benefit. About 2.5 c.c. of a 2 per cent. solution of an extract of spleen substance was injected and improvement was noticed after the seventh injection and a complete cure obtained after the fiftieth. Six months later the hemoglobin rate was 95 per cent.; the reds numbered 5,125,000; the whites, 6,800; the color index was 0.90. Equally good results were obtained in two other out-patients. Mikhailoff explains the favorable action of the spleen extract in the treatment of pernicious anemia by the presence of hormones which stimulate the functioning of the blood-making organs.

107. Cultivation of Tissues Outside the Body.—Veselkin and Kartashevsky claim that if the blood plasma of diabetics reduces the regenerative vitality of tissue, as is apparently evidenced by the serious course of skin lesions in diabetics, then the growth of tissues in plasma of this kind would be inhibited and be different from that in healthy plasma. They experimented on cats whose pancreas had been partially or totally removed under ether. Spleens of kittens were used for cultivation purposes. The spleen tissue showed normal growth in the plasma of both the pancreatectomized cats and the controls, demonstrating that the removal of the pancreas does not affect the regenerative power of the tissue cells, but only reduces the vital resistance.

108. Camphor in Pneumonia.—Markevitch advocates the use of 10 per cent. camphorated oil in the treatment of croupous pneumonia in doses of 5 c.c. four times daily or 10 c.c. twice a day of a twice stronger solution. The camphor was given by hypodermic injections combined with digitalis internally. The 226 male patients treated by this method gave 6.6 per cent. mortality, while of 322 treated without camphor 13.3 per cent. died. In 133 grave cases of pneumonia, 66 had no camphor treatment, with 48 per cent. mortality, while of 67 given the camphor as above only 15 died, namely, the mortality rate was only 22 per cent. Camphor thus considerably lowers the death-rate. The temperature usually fell by lysis; if a crisis occurred it was generally on the ninth day, instead of the seventh, which fact Markevitch explains by the gravity of the cases treated. Dyspnea is relieved, the respiration becomes quieter and deeper, the temperature subsides in two or three days; there is no delirium; the sputum decreases, the appetite reappears, and with the improvement of the general conditions recovery sets in. The local pneumonic process is little influenced by this treatment, though the area of consolidation was found diminished. The only by-effects were painful infiltrations at the points of injection, especially when the camphor got into the subcutaneous fat. There was suppuration at the point of injection in only two cases in the four years. Camphor has a bactericidal action, it is slowly absorbed, and thus gradually and quietly brings on lysis.

110. Diarrhea After Resection of Intestines.—When part of the intestines are excised, the remaining portions take on themselves the task of the resected part. If the processes of digestion and absorption continue normally, then the intestines are sufficient, but otherwise not. One of the annoying and dangerous signs of intestinal insufficiency is diarrhea. The question arises whether it is not possible to stop such a diarrhea by administering an astringent or opium. To settle this question, Brukhanoff made fistulas at various points along the gastro-intestinal tract of dogs, and studied the digestive processes after short-circuiting the bowel by resecting the jejunum or ileum. He found that with intestinal insufficiency the astringents and opium did not inhibit the passage of food through the intestinal tract, but rather accelerated it, and that these drugs acted unfavorably on digestion and absorption, and did not influence the decomposition of albuminoid substances. Therefore, he concludes, it is not advisable to administer astringents or opium in the diarrhea caused by intestinal insufficiency. The only rational treatment is dietetic.

111. Roentgen Exposures of the Thymus in Treatment of Exophthalmic Goiter.—Sinozersky studied on twenty patients with exophthalmic goiter the rôle played in its production by the thymus gland. Some were given Roentgen treatment of the thymus after two or three thyroid vessels had been ligated, but the majority had this treatment before any operative measures. The condition of the thymus gland was estimated by dulness on percussion over the sternum and to the left, after a tumor or aneurysm had been excluded by roentgenoscopy showing a shadow moving up and down the aorta during respiration, and by blood examination—increased numbers of lymphocytes (55 per cent.) and reduced polynuclears. Preliminary experiments on young dogs and rabbits showed that exposures to the Roentgen rays cause atrophy of the thymus. Roentgen treatment of Basedow's disease, directed against the thymus, with exposures every three or four days, gave marked improvement after five or six sittings. The pulse fell to 80 from 120 or 140; the goiter, the sweating, nervousness and exophthalmos decreased and the blood showed a decrease in the number of lymphocytes and increase of the polynuclears. As the skin in Basedow's disease is very sensitive to the Roentgen rays, an interval of three weeks is necessary before entering on another series of exposures. His conclusions are that the rôle of the thymus gland in the pathogenesis of exophthalmic goiter is established now beyond question.

112. **Epinephrin in Typhoid and Pneumonia.**—Mansvetova used epinephrin in infectious diseases, pneumonia, typhoid and paratyphoid, to improve the heart action. In order to determine the necessary dose of the 1 per thousand solution of epinephrin, she injected hypodermically 0.5 c.c. in 13 patients; 0.75 c.c. in 10 patients, and 1 c.c. in 7 patients. She found that 1 c.c. caused a rapid and considerable rise of the blood-pressure during systole, while the diastolic decreased; 0.75 c.c. also raised the blood-pressure, but more gradually. The action is rather inconstant; the systolic increases, the diastolic falls. The dose of 0.5 c.c. caused a less pronounced increased blood-pressure, and in these doses, given every hour and twenty minutes or every ninety minutes, the weakened circulation could be maintained for a long time. These small doses do not affect the peripheral circulation, but cause dilatation of the coronary arteries of the heart, thus improving the circulation in the cardiac muscle and its nutrition. The larger dose of 1 c.c. is indicated when a rapid rise in the blood-pressure is necessary, as, for instance, in postoperative shock, collapse or acute poisoning, but in acute infections so large a dose should not be used, as the heart under the toxic influences may be unable or too weak to respond to such a dose.

114. **Laboratory Anthrax Infection.**—Popoff reports a case of fatal septicemic anthrax of the left bronchus in a patient who had contracted this disease in a laboratory in which anthrax vaccine was prepared. The organs showed parenchymatous changes, such as are caused by any toxemia. He concludes that death from anthrax is caused not by mechanical, but by toxic influences, and that the infection may take place sometimes through aspiration or inhalation. Prophylactic vaccination against anthrax, serodiagnosis and serotherapy are of tremendous importance, especially in Russia, he says, where in the army 61 persons die annually from this cause on an average, and during the years 1904 to 1908, 80,498 persons and 218,956 horses and cattle throughout Russia were affected with it.

115. **Nucleoproteid of Dysentery Bacillus.**—Neitz obtained from bodies of Shiga-Kruse bacilli an albuminoid substance with the chemical properties of a nucleoproteid. The latter proved to be extremely toxic for dogs and rabbits, as death would occur on the second or third day after injection into rabbits in the ear, abdominal cavity or under the skin. The temperature falls by 5 or 9 degrees C., general convulsions set in, collapse, dyspnea and paresis of the hind limbs make up the clinical picture of poisoning, with frequently diarrhea two or four hours after the injection of the nucleoproteid. The blood culture always proved negative. The serum of animals immunized by repeated injections of dead Shiga-Kruse bacilli (heated to 60 or 65 C.) precipitates the nucleoproteid from its solution. The serum of rabbits rendered immune by repeated intravenous injections of 1 per thousand nucleoproteid solutions agglutinates Shiga-Kruse bacilli, but no other type of dysentery bacilli.

116. **Washing the Blood.**—Mikhailoffsky connected with long tubes the upper end of a bottle with the right femoral artery of a dog and the lower end with the right external jugular vein. The bottle was filled with Locke's fluid. Having removed the clamps, he let the arterial blood run into the bottle, and from the latter pass with the Locke's fluid back into the jugular vein. When a fourth of a liter of blood had been let out, he connected the femoral artery directly with the jugular vein through a tube 40 inches long, and he could see and feel the pulsation of the jugular vein—an actual artificial pulse. The Locke's fluid saturated with blood was then replaced by a new quantity of the same fluid, without blood, and the experiment was repeated. About two-thirds of a liter of blood was thus removed, and neither the pulse nor the respiration showed change. These experiments suggest that Locke's fluid may replace normal blood, preventing its coagulation in vitro, that the blood may be greatly diluted with it without fatal complications for the animal, that an artery may be directly connected with a distant vein, no thrombus forming, and that an artificial venous jugular pulse may be obtained, and that the blood may thus be safely washed out in uremia, cholemia, snake poisoning, ptomain poisoning, etc.

118 *Radiotherapy of Lupus and of Bone and Joint Tuberculosis. (Om Anvendelse af kunstige Lysbade ved Lupus vulgaris og kirurgisk Tuberkulose.) A. Reyn and N. P. Ernst. Concluded in No. 44.

117. **Convulsions in Whooping-Cough.**—Sørensen has noticed that when convulsions occur in the course of whooping-cough they are generally accompanied by fever which may run very high. This suggests that the same cause inducing them may have a paralyzing action on the heat-regulating center. In the 26 cases he has encountered, 21 terminated fatally; the convulsions in 15 of the fatal cases developed once at the beginning of the disease, five times in the second and five times in the fourth week, and once the third, fourth, sixth and eighth weeks. The date is not known in 6. Only 5 patients with the convulsions recovered, but in the majority of the fatal cases death was due to pertussis pneumonia, the convulsions being secondary to this when they did not develop until the fourth week or later. One child of 3 had fever and cramps in his arms with meningitic symptoms and unilateral facial paralysis for ten days before the pertussis manifested itself. As this developed, the other symptoms subsided completely. In only one other case were there symptoms on the part of the meninges, and both these children were 3 and 5; all the others were infants. In one of the few cases that came to necropsy, thrombosis in the longitudinal sinus was pronounced, but the bacteriologic findings were negative. The children who had convulsions were all without exception of the spasmophilia type, the nervous system unstable.

118. ***Radiotherapy of Lupus and Bone and Joint Tuberculosis.***—Reyn and Ernst give a number of illustrations "before and after" treatment in forty-two cases of lupus, all but five being very old and mutilating cases. They prefer to call this method of treatment artificial heliotherapy, as their aim is to use a light which resembles direct sunlight as closely as possible, and this they think is the carbon arc light. Of the thirty-seven cases rebellious to all previous measures, nine were completely cured and twenty remarkably improved, and the improvement is still continuing. Two of the patients died soon after the treatment had been begun; the interval since has been too short in the other cases for estimation of the final outcome. They were much impressed with the improvement in the general health under the artificial heliotherapy. The universal chemical light bath was Finsen's ideal, they state, rather than intensive local exposures to the light. The light baths were given daily or two or three times a week; some patients were cured with fifty-one exposures; the one requiring the longest course had 208 exposures; the one requiring the longest course had 208. The baths were never over two and a half hours in duration.

THE RELATION OF THE MEDICAL SCIENCES TO CLINICAL MEDICINE *

FREDERIC S. LEE, Ph.D.
Dalton Professor of Physiology, Columbia University
NEW YORK

In the medical curriculum there has come to exist a distinction between the medical sciences and the clinical subjects. At the middle of the course of four years there is a more or less sharp break — the student drops his science, the pursuit of which he has sometimes looked on as a burdensome, if not superfluous, experience, and turns abruptly to what he is often inclined to regard as the real thing in his preparation for professional work. Even the medical practitioner sometimes assumes a similar attitude toward the two groups of studies, and teachers of clinical medicine have not always been free from the encouragement of such a notion. That such an idea is wrong goes without saying, for it receives no sympathy from the best minds of the medical profession. Yet this arrangement of studies has not always existed; the present medical curriculum, which in its main features is essentially the same the world over, is a product of evolution, and one of the striking incidents of its recent history is the prominence that has been acquired by the medical sciences. It may be helpful to look into the rise of these sciences in some detail.

EVOLUTION OF THE MEDICAL SCIENCES

Anatomy is the original and it still remains the traditional medical science. For centuries religious and social prejudices against the dissection of the human body confined anatomic study largely to the lower animals; nevertheless, even in the days of the Alexandrians, three hundred years before Christ, students of medicine probably had opportunities to witness frequent human dissections by Herophilus and Erasistratus and their followers. Later human dissection fell into disrepute and then revived, and by the fourteenth or the fifteenth century it became a part of the routine of medical instruction at the leading European universities. It received a new impetus from the great anatomists of the sixteenth century, led by Vesalius, but even then the students had little anatomic opportunities except to look on at demonstrations by the leaders or, more commonly, by the barbers or surgeons who actually handled the organs and tissues. It was not until the eighteenth century that the use of the scalpel by the student himself became at all common; and from that time until almost the present day the dissecting-room has been regarded as the student's proper abiding place during all his hours outside the lecture or clinic. It is obvious — and to no one more than the anatomist himself — that the gross structure of the human body presents a limited field of study for both the investigator and the undergraduate. In the last fifty years it has been supplemented and illumined by the study of microscopic structure, of embryologic development, and of genetic relationship, and has thus become broader and more helpful than before. But even with these additions, anatomy does not now occupy, and can never hope to regain, its former unique position as the one medical science deserving a separate place in the medical curriculum. Anatomists are entitled to great credit for having impressed on medicine the importance of their science during all the centuries; it helped to raise medical art above the degrading empiricism and speculation with which it was beset; it long kept alive the scientific spirit; and if its preeminence in medical study is now lessened this change must be ascribed, not to the fault of anatomy or anatomists, but largely to the general scientific renaissance through which we are passing.

Physiology, like anatomy, is one of the classical medical sciences. It is of prehistoric origin, for doubtless men always interested themselves in the working of their own bodies. At the time of the height of Grecian culture and of Alexandrian wisdom it had risen to an honorable place among the departments of human knowledge. Five hundred years later it was enriched by the labors of the immortal Galen. Through the middle ages it slumbered. In the sixteenth century it received an undying impulse from William Harvey and his discovery of the circulation of the blood, and from that time to the present it has had an unbroken advance, more rapid with each succeeding decade. During the century that has just closed, along with the passing of the doctrine of vitalism and the rise of the conception of the conservation of energy in physics and that of oxidation in chemistry, physiology has developed along two main lines and has come to be known as the science of the physics and chemistry of living matter; and as the content of the science augments, these two lines, although possessing a common aim, are forced by their different points of view and their different technical methods to diverge from one another. As a matter of medical education physiology had no separate status of its own until the eighteenth century. It was taught as an integral part of anatomy, the function of a part being naturally considered in connection with its structure. In the eighteenth century physiology came to be recognized as deserving of specific mention in the medical curriculum, but it

* Address delivered at the opening of the session of 1914-1915 of the Columbia University College of Physicians and Surgeons.

was still united with other subjects, the choice of its companion apparently being determined by local circumstances. When the first medical school of Kings College, the forerunner of Columbia, was established in 1767, physiology and pathology together constituted one chair. The first physiologic laboratory was established at Breslau in 1839. The subject was first taught by means of lectures exclusively, but during the nineteenth century demonstrations gradually crept in. In this country the demonstrative teaching of Dalton, who came to the College of Physicians and Surgeons in 1854 fresh from the inspiring laboratory of Claude Bernard, created much enthusiasm and inaugurated a new era for American students of medicine. It is within a period of only about twenty-five years that laboratories of physical and chemical physiology for the general body of students have become common, and undergraduate students at last after all the centuries of growth of the science have been given the privilege of learning it. In Europe physiologic laboratories are not so well equipped for instruction as they are in this country, and it may truthfully be said that few medical practitioners in any country who have passed the age of fifty have had adequate opportunities to learn the methods of this science, to them most indispensable, or to steep themselves in its spirit.

Although many individual diseases were well known to the ancients, pathology, the science of diseases, was necessarily largely a matter of theorizing until after the beginning of the revival of learning. By the sixteenth century those who dissected the human body began to be interested in the finding of abnormalities in the organs. This became gradually more and more common, and a mass of pathologic knowledge slowly accumulated; but it can hardly be said to have been organized for two hundred years and until the Italian, Morgagni, published in 1761 his remarkable five books on "The Seats and Causes of Disease as Investigated by Anatomy." There for the first time with any degree of completeness gross anatomic lesions were considered in relation to the clinical records of the diseases, and the science of pathologic anatomy may be said to have been born. It required still another hundred years before the cell conception was introduced into pathology by the great Virchow. Physiologic, or experimental, pathology was even slower in coming into being, for it could not well appear before normal function had become known. As with physiology so in pathology all teaching was at first didactic; later necropsies were employed for instruction; then the microscope was brought in for demonstrating the changes produced by disease in tissues; but not till about thirty years ago did undergraduate medical students have an opportunity themselves to prepare microscopic sections and examine them in the laboratory. The receiving of formal instruction in experimental pathology is still the privilege of the favored few.

Drugs have been used for therapeutic purposes from the earliest times, and the history of drug treatment is perhaps the strangest in all medicine. Here we see crude empiricism at its very worst. Although the ancients used many drugs intelligently the materia medica of the time of Queen Elizabeth contained, among remedies which may still be rationally used to-day, such monstrosities as cast-off snake's skin, dried vipers, foxes' lungs, spiders' webs, a plaster "compounded of viper's flesh, with live frogs and worms," oil of ants, oil of spiders and earthworms, "oil of puppies boiled with earthworms," cat ointment, and "moss from the skull of a victim of violent death." During the seventeenth and eighteenth centuries medical schools attempted some improvement by establishing botanical gardens to which students were expected to resort in order to study growing medicinal herbs, a strategy for inducing mental exercise which does not seem to have appealed strongly to the student mind. Pharmacology, however, the exact science of the physiologic action of drugs, did not appear until the nineteenth century when Magendie, the French physiologist, showed its possibilities. Its first laboratory was opened in Dorpat in 1856. Young as it is as a science, it is still fighting its way for independent laboratories and an adequate place in the medical curriculum.

But the youngest of all the medical sciences is bacteriology, and it has had the most rapidly brilliant career. All the world knows that its founders were Louis Pasteur and Robert Koch, and that less than half a century has passed since they began their epoch-making studies of the relation of micro-organisms to human diseases. It is since then that the most of the known species of bacteria have been discovered, and, what is of the greatest importance medically, the mutual physiologic relations of bacteria and their living hosts have become in a considerable degree elucidated. A knowledge of these physiologic relations has given us serums and vaccines and their therapy, and the whole fabric of immunity. As rapid as has been its growth, almost as quickly has bacteriology won its place in the medical curriculum, and it is the poor school now that does not possess a laboratory in which undergraduate students may personally experiment with disease germs.

From this brief glance at the evolution of the medical sciences we see that, with the exception of anatomy, they all have taken their places as separate branches of medical study during a period comprising even less than one hundred years. As time passes, therefore, their position within medical schools has been achieved only very recently. Moreover, the sciences that have thus come quickly into being as factors in medical education are chiefly those that have to do with function rather more than with structure — they are physiologic rather than morphologic sciences. Hence they are sciences that progress by means of experiment rather than by simple observation. In detail they include physiology itself, physiologic and pathologic chemistry, physiologic pathology, pharmacology and the greater part of bacteriology. This fact of the great inroad into medical education of these physiologic sciences is, I venture to think, a very remarkable and significant fact; for it indicates that they are of vital importance to the practitioner of medicine. Their influence is threefold: In the first place, they supply the future practitioner with a vast mass of systematized knowledge of the ways in which the complex human body performs its work, physical and chemical work, both in health and in disease; they show how this work may be modified by drugs and other remedial measures; they show how perturbations of bodily functions may be prevented and how normal function, when once disturbed, may be restored. In other words, they give to the future practitioner the basis for his technical procedures and teach him the reasons therefor. Moreover, they show him how this knowledge has been obtained, where it is still incomplete, and the ways in which it may be added to. In the second place — and this is of equal if not greater importance — they reveal to the future practitioner the nature of the scientific method; they show him how many of the best of the world's minds have proceeded when confronted by the problems of nature, how they have analyzed and clarified these problems, how they have devised experimental methods for the purpose of investigating them, and how they have solved them. They teach him the nature of causation, the necessity of finding causes if natural phenomena are to be understood, and the fallacy of the idea, which is far too prevalent in medicine, that that which precedes is necessarily the cause of that which follows: that, for example, when a certain drug is given and a cure follows, the cure is necessarily due to the drug — *post hoc, ergo propter hoc*. They show the importance of exactness in all scientific work and how as the medical sciences have advanced they have become constantly more exact. Moreover, they show that the problems of the practitioner are simply problems of Nature — the problems of the bedside are the same in kind as the problems of the laboratory, and they demand for their solution the attitude of the man of science. In the third place, if instruction in the medical sciences is what it should be, it imbues the student with a love for science and the scientific method; it fills him with the scientific spirit, without which no follower of medicine can attain the best.

CLINICAL MEDICINE

Now let us turn from the consideration of the sciences to that great body of knowledge which constitutes modern clinical or practical medicine. It is a wonderful achievement of man. It represents the efforts of countless human minds, each working during his brief generation, while the whole is the product of the restless labor of centuries. It has had a manifold origin — individual experience, philosophical theory, speculation that cannot lay claim to the title "philosophical," and occasionally chance and accident have all contributed their share, and through it all but rising into commanding prominence in modern times there can be found the desire to discover causes, to connect causes and effects, to control effects by influencing their causes, and to substitute rationalism for authority — and this is the essence of science. If the history of medicine is to be summarized, it may be conceived as a constant conflict between empiricism and speculation on the one hand and science or something that corresponds to science on the other. Each side has had its victories and its defeats; each has had its periods of ascendency and its periods of decline; neither side has been wholly wrong; medicine at all times has been a mixture of the two; nevertheless the scientific conception and the scientific method have gradually won their way, they have demonstrated their merit, and they are bound to prevail in the end.

A striking chapter from the history of this conflict is illustrated by the course of medicine in Germany during the past century. In the first half of the century it fell on evil ways and descended to a low level. In 1854 — only sixty years ago — the clear-sighted Virchow wrote:

> German medicine on account of its views and dissenting "schools" has become the laughing stock of the world.

Oertel has graphically described the situation of the time. He says:

> There did not exist a well-founded universal scientific method of thought, investigation or teaching, but only opposed and battling "schools" and "systems" of medicine and therapy, such as homeopathy of Hahnemann, polypragmasia, Rademacher's system, Priessnitz's system, therapeutic nihilism, eclecticism, Bouillaud's bleeding to unconsciousness of the patient, Dietl's absolute condemnation of bleeding as a criminal offense (1849), Mesmerism and others. They formed the source of endless and senseless discussions, for they were all speculative and contributed much to the entertainment of their pompous defenders and the laity but not to the benefit of their patients. . . . It was not even a time of crude empiricism, but a fantastic period which, like a nightmare in individuals, occasionally arises during the life of a nation.

And yet Germany was then on the threshold of a great reform, for the medical sciences — pathologic anatomy, pathologic histology, physiology and pharmacology — were beginning to show to clinical medicine the pathway to higher things, and it was not many years before Germany had become the world's medical leader. But notwithstanding the triumphs of science the constituent parts of the great mass of modern medical knowledge are still of very unequal value; empiricism and speculation have not yet ceased to be; they are still the bane of medicine, and it is still necessary to contend against them.

As with everything that is of ancient origin, so in clinical medicine tradition is very potent. It is surprising to see to what an extent modern medical theories and practices come from the ancients and presumably therefore are purely speculative or empiric in their beginnings. This does not mean that they are therefore necessarily wrong, but their early ancestry always arouses suspicions in these days when science is smashing tradition right and left. Thus the fantastic doctrine of the humors, the beginnings of which seem to antedate all historical writings, still existed at the beginning of the nineteenth century. The pernicious fashion of blood-letting was practiced not only by Hippocrates four hundred years before Christ, but by the disciples of Hippocrates twenty-two hundred years after his death. The old treatment of pneumonia still persists, and from 20 to 40 per cent. of the patients still die. Quinin was used successfully for malaria by the Spanish invaders of South America in 1638 — an excellent example of the empiric introduction of an invaluable drug, the use of which medical science has now shown to be justified by its specific action on the malarial organism. A well-known American neurologist tells me that he frequently uses one of Galen's prescriptions and finds it very helpful. The celebrated Papyrus Ebers is said to record the fact that arsenic was used in the treatment of cancer even in ancient Egyptian times. The practice of greatly restricting the diet in patients suffering from acute febrile diseases was advocated and used by the "Father of Medicine," and is still practiced extensively, although the careful scientific work of Coleman now shows that it is to the disadvantage of the patient. The achievements of bacteriology have destroyed at once long-held and cherished traditions regarding the course, treatment and prevention of infectious diseases, and have enabled surgery to pass from an ancient to a modern art. Recent advances in our knowledge of the physiology of nutrition bid fair to place the traditionary topic of dietary treatment at last on a rational basis. With very many of the customary usages of present-day medicine it would probably be extremely difficult, if not impossible, to search out their origin, but every doctor who employs them should at least be able to justify their continued employment. One of the dangers to which students are exposed is that of learning the methods of their instructors without the reasons therefor and blindly carrying over the same methods into their own practice. This procedure, which may be called learning by inheritance, while implying a gratifying degree of respect on the part of the student for his professor, is not to be recommended, for while it may make a ready man, it does not make a full one. All young practitioners are subjected to this danger, often during their hospital service, and especially while serving on the staffs of the dispensaries. They there find that particular lines of treatment have, it may be, been long in use, certain prescriptions have become hallowed by age. It is not always easy to obtain and still less easy to remember their formulas, and to question their reason or practicability is not expected. The path of least resistance is to accept them, and this the younger doctor proceeds to do. What dispensary physician has not prescribed, without further thought of their constituents or physiologic actions, "Loomis' tonic," "tonic No. 6," "whooping-cough mixture No. 4," "epilepsy mixture," "Lockwood's sedative," "Pill Janeway," or their equivalents? Such a practice becomes too often mere mechanical routine, detrimental to the future growth of the scientific physician. I have heard it related of the great French physiologist, Magendie, that he was once demonstrating to some of his colleagues a new fact which he had discovered. His friends were skeptical of its validity and remarked that it could not be true because it was contrary to "the law of the membranes" — whatever that may be. To which the courageous savant replied that he knew no law of the membranes, but that there before them was the demonstrated fact. Adherence to tradition is right when tradition can justify itself, but a wholesome and well-balanced skepticism as to traditional medicine is the only safe and sure attitude of mind for the physician who would be progressive.

It is customary in these present days of great medical achievements to dwell on these achievements and to congratulate ourselves on what we have been able to accomplish. This is justified. Medical advance has indeed been marvelous; both medical science and clinical medicine are daily making magnificent conquests, and for this success no one has a greater admiration than I. But while in the face of such success self-congratulation is permissible to us, self-complacency, I submit, is not, for it cannot be denied that medicine has glaring deficiencies. It is of some of these that I wish, with your permission, now to speak—although in no pessimistic spirit. Consider the matter of diagnosis. Dr. Richard Cabot[1] has recently made a very frank and courageous, but very significant comparison, in the cases of three thousand patients who have died at the Massachusetts General Hospital, of the pathologic conditions actually found at necropsy and the diagnoses made during life from the clinical findings. He found the percentage of mistaken diagnoses to be as in the accompanying tabulation:

PERCENTAGE OF MISTAKEN DIAGNOSES FOUND BY CABOT

Acute nephritis	84	Phthisis, active	41
Acute pericarditis	80	Aortic stenosis	39
Hepatic abscess	80	Septic meningitis	36
Chronic myocarditis	78	Brain hemorrhage	33
Vertebral tuberculosis	77	Mitral stenosis	31
Bronchopneumonia	67	Gastric cancer	28
Renal tuberculosis	66.7	Tuberculous meningitis	28
Suppurative nephritis	65	Cerebral tumor	27.2
Peptic ulcer	64	Chronic glomerulonephritis	26
Acute endocarditis	61	Lobar pneumonia	26
Hepatic cirrhosis	61	Cancer of colon	26
Thoracic aneurysm	50	Aortic regurgitation	16
Chronic interstitial nephritis	50	Typhoid fever	8
Miliary tuberculosis	48	Diabetes mellitus	5

The average of mistaken diagnoses in these twenty-eight diseases is 46.5 per cent., or nearly one-half, and this in one of the leading hospitals of the country, where all available aids to correct diagnosis ought to be had! Dr. Cabot says: "The study of the details in these cases before and after death convinces me that, for the present and under the present limitations of diagnostic method, few of the mistakes tabulated above could have been avoided. . . . They mirror the methods of an average up-to-date hospital." Professor Orth, director of the Pathological Institute in Berlin, is said to have made the statement that "of all appendixes that have been submitted to him for examination by conservative surgeons with the clinical diagnosis of appendicitis, as many as 17 per cent. showed no disease." Dr. Starr tells me that the diagnosis of the location of brain tumors is a matter of probability, not of certainty, in 40 per cent. of the cases. We can easily identify a disease in a dead man, but what is needed is more accurate methods of finding it in the living one.

Does treatment afford us a greater cause for self-congratulation? In 1909 of the 732,538 deaths which occurred in the registration area of the United States, 90,868 resulted from pneumonia and other diseases of the respiratory organs; 90,456 from diseases of the circulatory organs; 81,720 from tuberculosis; 66,803 from nervous diseases; 48,430 from nephritis; 44,648 from diarrhea in infants; 38,020 from cancer and other tumors; 10,722 from typhoid fever, and 10,358 from diphtheria. Moreover, during the ten years from 1900 to 1910 there was a large increase within the registration states in the death-rate from certain forms of disease: diseases of the arteries, 396 per cent.; diabetes, 60 per cent.; organic diseases of the heart, 39 per cent.; cancer, 30 per cent.; nephritis, 18 per cent.; cerebral hemorrhage, 18 per cent., and cirrhosis of the liver, 14 per cent. When we realize that the registration area of the United States covers a comparatively small portion of the inhabited world's surface, we can form some notion of the huge army of the world's people who die each year from diseases for which there ought to be remedies. And the pronounced increase in the number of victims of some of these maladies reveals that medicine is not advancing as rapidly as are certain destructive agencies.

Sir William Osler's optimism in all things medical is pronounced, and hence it is the more interesting to read his words of prognosis. He says: Of typhoid fever: "Of the 1,500 cases treated in my wards, 9.1 per cent. died." Of pneumonia: It "is one of the most fatal of all acute diseases, killing more than diphtheria, and outranking even consumption as a cause of death." Of bronchopneumonia: "The death-rate in children under five has been variously estimated at from 30 to 50 per cent." Small-pox "in unprotected persons . . . is a very fatal disease, the death-rate ranging from 25 to 35 per cent." Of diabetes mellitus: "Personally I have not known an instance of recovery in a child." Of cirrhosis of the liver: "The outlook is bad." Of chronic Bright's disease: "The prognosis is extremely grave. . . . It is an incurable affection." Of pernicious anemia: "The ultimate prognosis in a great majority of cases is bad." Of leukemia: "Recovery . . . is practically unknown." Of diseases of the myocardium: "The outlook in affections . . . occurring late in life is extremely grave." Of aneurysm: "The outlook in thoracic aneurysm is always grave . . . in abdominal aneurysm is bad." Of Addison's disease: "The disease is usually fatal." Of the prognosis in epilepsy Osler frankly confesses: "This may be given to-day in the words of Hippocrates: 'The prognosis in epilepsy is unfavorable when the disease is congenital, and when it endures to manhood, and when it occurs in a grown person without any previous cause. . . . The cure may be attempted in young persons, but not in old.'"

THE SCIENTIFIC AND THE PRACTICAL

From what I have said it is, I trust, sufficiently obvious that notwithstanding the high character of clinical medicine in many of its aspects and the great advances which it is making in many of its divisions, there is still everywhere imperfection, and serious imperfection, to be eliminated. Medicine is still very far from its ideal, which, I take it, is to maintain the individual in health, in other words in a physiologic state, if possible; and if he has lapsed from that state, to restore him to it. How can such an ideal best be attained? Two things are here needed.

In the first place, there must be a greater development of the medical sciences. "Medicine," says Dr. Victor C. Vaughan, the accomplished President of the American Medical Association, "consists of the application of scientific discovery to the prevention and cure of disease. All else which may go under the name of medicine is sham and fraud." The medical sciences have already accumulated a huge mass of material which is at the service of those who would utilize it in the treatment of disease. And yet there is still pioneer scientific work to be done everywhere. The more one labors to unravel the mysteries of the human body, the more intricate it seems to be; the farther one penetrates, the more one sees of unsolved problems. In the present stage of the evolution of the medical sciences the chief labor must be performed by the aid of experimentation, and here physiology, physical and chemical, must lead the way. The establishment of hospitals for the care of the sick and even for clinical research, the giving of large sums of money for the investigation of specific diseases, while having a certain value to the human race in the immediate saving of imperiled human lives, do not provide, I believe, the most direct path to the desired goal. The endowment of physiologic research, the dedication of a host of bright minds to the unraveling of the intricacies of the living mechanism, the learning of the ways in which the mechanism acts in health — herein, and herein chiefly, lies the secret of rapid, comprehensive medical advance. When once we know the normal activities of the body — and often while learning these — we can the more quickly discover the abnormal activities, and then the way to bring the diseased body back to the normal will soon be devised.

In the second place, in order to attain its ideal more completely, clinical medicine must be more fully saturated with a knowledge of the medical sciences, with scientific method and with the scientific spirit. The clinician must know more of what the physiologist, the pathologist, the pharmacologist and the bacteriologist are doing. Their discoveries are vital to him. Moreover, he must have so acquired the scientific habit of looking at the problems of nature that instinctively, when confronted by a case of disease, he will attack it, not as a matter of routine, not as he may have attacked a hundred other cases of the same disease before, for no two cases are wholly alike—nature never copies her works of art exactly—but as the man of science attacks one of his laboratory problems, with the critical, analytic spirit of the investigator, eager to find new facts and new points of view, eager to discover causes and relate them to effects. The problems of clinical medicine differ from the problems of the laboratory in this important respect: namely, that, while in the laboratory the investigator can establish the conditions under which he is to study, at the bedside the conditions are already established for him and he who is to officiate there must accept them. This makes his problem all the more difficult of solution.

Moreover, the practitioner in his professional capacity rarely has an opportunity to see the complex living mechanism with which he has to deal, in its normal state. When it is brought to him it is out of order, something has gone wrong, and the balance is upset. This may complicate the matter still more, for while it may be obvious that some of the parts are not behaving properly, it may not be so evident where the primary seat of the trouble lies. The practitioner cannot take the mechanism apart, as can the laboratory worker, but must necessarily deal with symptoms, and here is one of his dangerous pitfalls. For one who has learned the conventional clinical routine it is easy enough to prescribe for symptoms; but prescribing for symptoms alone is the resource of the ignorant and the inert. In current discussions of diseases we often hear that learned and awe-inspiring word, "syndrome," which is full of mystery to the uninitiated. A syndrome means a certain group of symptoms which are found to occur together. They may be related obviously or they may involve widely diverse organs. While the word is used in different fields of medicine it has become especially prominent in neurology, which already recognizes more than fifty different symptom complexes. Syndrome is a convenient word, but there is a real danger in its use, and this lies in regarding it as a finality. The symptoms, or the group of symptoms, is nothing if one cannot go deeper and find the anatomic and physiologic conditions which underlie the obvious signs. "Many neurologists think," says Dr. Tilney, "that when they have got down to a mass of symptoms, they have got to the end. Really they haven't begun. They are looking through the wrong end of the telescope." The excellent analytic work of Dejerine and von Monakow — and not to go to a greater distance from home — in our own laboratories and clinics the work of Professors Pike and Tilney indicate the advantages of placing clinical neurology on an exact anatomic and physiologic basis.

But it is not in nervous diseases alone that critical analysis must be carried beyond the symptoms to the underlying focus of the disease. One of the leading orthopedists of America told me a few days ago of a severe case of arthritis which he had recently had in his practice. The patient had been bedridden for several months, unable to move, except with difficulty and much pain. The inflamed and stiffened state of the joints was obvious and seemed to call for local treatment. The physician, however, caused a thorough chemical and physical examination of the patient to be made, during which a roentgenogram revealed the presence of unsuspected local abscesses at the roots of several of the teeth. The removal of these affected teeth resulted in the prompt recovery of the patient from his joint disease. In the opinion of this physician every orthopedist ought to have at his command a competent physiologic chemist with a well-equipped laboratory.

Prof. J. Whitridge Williams, of Johns Hopkins University, in a recent address as president of the American Gynecological Society, severely criticized the members of that society for not taking a more prominent part in the advancement of obstetric knowledge, and he added that universities ought to equip and maintain women's clinics "liberally provided with laboratories for the anatomical, chemical, pathological and physiological investigation of gynecological and obstetrical problems." The staffs of hospitals should be increased to include, in addition to the always existing pathologist, a physiologist, a physiologic chemist, a pharmacologist and a bacteriologist, competent to observe human beings from their respective points of view. If this were done, not only could their rich stores of knowledge and experience be brought to the service of the clinician, but they in turn could have wider opportunities than their laboratories afford for the investigation of their problems and the broadening of their knowledge. Their work should by no means be restricted to experimentation on animals, but they should have abundant opportunities for the legitimate extension of their observations to human beings. "How helpful it would be," says Sir William Osler, "if clinicians had always at hand skilled physiologists, pathologists and chemists to apply their most advanced technic to clinical problems, and not the technic alone, but the biological and chemical principles upon which medicine as an exact natural science is founded." This could be made a powerful agency in drawing together the two divisions of medicine, now unfortunately far too divergent.

IMPORTANCE OF SCIENCE TO THE STUDENT

At the beginning of this address I spoke of the distinction that has come to exist in the medical curriculum between the medical sciences and the clinical subjects, and of the sharp break that occurs at the middle of the four years' course when the student drops his science and turns eagerly to the clinic and all that it is supposed to bring to him. Such a break ought never to be. One spirit, and only one, ought to permeate the undergraduate's four years, and that should be the spirit of untiring devotion to science, the master to whom all must pay their whole allegiance who wish to attain the best. Those who teach the medical sciences have not done their whole duty if they have not convinced their students that the sciences provide the key by which all that comes after may be unlocked; and the teachers of the clinical subjects have likewise failed if they do not hold to a rigid scientific ideal in their outlook over the details of practical medicine. Nor must this ideal be forgotten any the more during the two years of the hospital internship. After that the young doctor, sent forth on a world that is more or less skeptical of the efficiency of medicine and inclined to turn to fads and cults, must decide for himself what his course will be. He will find two paths open to him—the path of tradition and the path of progress. With the one his professional life will consist of a long succession of yesterdays, filled with the contemplation of what has been; with the other he will be ever reaching out for what to-morrow may yield. To him medicine may be either a trade or a profession. A man who is to follow a trade learns as an apprentice certain procedures, and thereafter it is his task to follow those procedures implicitly. The routine of a trade once learned is learned for a lifetime. It is possible to practice medicine in the same unintellectual way and to win what the world may call success. But there exists a higher type of physician. He it is who recognizes that his is a learned profession and who rises to the full dignity of it. Fortunate will be the life of that young man who feels irresistibly the call to the higher ideal.

GASTRO-INTESTINAL STUDIES

IV. DIRECT EVIDENCE OF THE SECRETION OF A GASTRIC JUICE OF CONSTANT ACID CONCENTRATION BY THE HUMAN SUBJECT

MARTIN E. REHFUSS, M.D.
AND
PHILIP B. HAWK, Ph.D.
PHILADELPHIA

The question of gastric acidity has received considerable attention in recent years. It has been demonstrated quite conclusively, for example, that the phrase "the normal gastric juice of man contains about 0.2 per cent. of hydrochloric acid" can no longer go unquestioned. On the basis of older experimental evidence a rather high acidity (from 0.5 to 0.6 per cent.) was accorded the gastric juice of such lower animals as the cat and dog, whereas man was found to remain content with an acidity in the vicinity of 0.2 per cent. More recent experiments,[1] however, indicate that the actual acidity of the gastric juice of man is very similar (from 0.4 to 0.5 per cent.) to the gastric juice of the cat and the dog.

Pawlow,[2] on the basis of experiments made principally by his colleague Ketscher, enunciated the belief that "the gastric juice as it flows from the glands possesses a constant acidity." Various observers have repeatedly demonstrated both clinically and experimentally that there are pronounced variations in the gastric acidity. These variations Pawlow would explain as due mainly to the varying lengths of time the juice was in contact with the alkaline mucosa of the stomach. In substantiation of this view, he brought experimental evidence to prove that the juice which was secreted rapidly possessed a higher acidity than juice which was secreted more slowly, the latter form of juice having been more thoroughly neutralized because of its longer or more thorough contact with the mucus of the mucosa. The theory of constant acidity received further support in certain of Pawlow's tests on fasting dogs equipped with the Pawlow pouch. When such animals were subjected to "sham feeding," the acidity of the gastric juice remained constant notwithstanding the fact that the chlorid content of the animal's body was very markedly deficient. "Sham feeding" finally failed to evoke any secretion of gastric juice; but so long as there was any output of juice, it was of constant acid concentration.

Thompson, Ed. 2, p. 32.

Boldyreff[1] is the latest to assert a constant acidity for the human gastric juice. This investigator declares that the juice as poured out by the gastric glands has an acidity of about 5 per cent. This secretion of relatively high acidity is rapidly neutralized through the instrumentality of the regurgitated duodenal juices, the prime factor in the neutralization being the pancreatic juice. The "optimum" acidity is placed by Boldyreff at from 0.15 to 0.2 per cent., and the aim of the reflux of alkaline material into the intestine is to maintain the "optimum" acidity. If alkaline, neutral or faintly acid juices are introduced into the stomach, they are believed to excite an additional outpouring of the highly acid juice in order that the acid concentration of the stomach contents may be maintained at the "optimum."

In experiments on cats which had been subjected to the Pawlow pouch, Carlson, Orr and Brinkman[3] have recently demonstrated that "milk, whether ingested voluntarily or given forcibly, yields practically identical quantities and concentrations of gastric juice."

Wills and Hawk,[4] in a series of tests on the influence of water drinking with meals, demonstrated that the excretion of urinary ammonia was directly proportional to the volume of water ingested. They concluded that "the uniform relationship between water ingestion and the ammonia output might perhaps be considered as indicating that there was an attempt on the part of the gastric cells to maintain a uniform acid concentration."

Kersten[5] reports data which might be interpreted as demonstrating that the dog under some circumstances at least secretes for rather long periods a juice which is approximately constant in its acid concentration. The acidity values for a period of six hours after feeding 600 c.c. of milk are submitted in Table 1.

TABLE 1.—ACIDITY VALUES GIVEN BY KERSTEN

Hour	Hydrochloric Acid Per Cent.
First	0.49
Second	0.55
Third	0.55
Fourth	0.55
Fifth	0.48
Sixth	0.45

Certain experiments of Chighin[6] are also of interest in this connection. This author demonstrated that the introduction of 150 c.c. of water into the large stomach of a Pawlow dog evoked a secretion of 2.1 c.c. of gastric juice in the pouch, the juice containing 0.42 per cent. of hydrochloric acid, whereas when 500 c.c. of water were used a much more copious flow of juice, 7.2 c.c., was obtained, but its acidity was approximately the same (0.45 per cent.) as before.

Lönnqvist[7] has also reported data which may be interpreted as indicating, in some cases at least, that the juice as secreted from the Pawlow pouch, after the introduction of water and salt solution into the large stomach, is practically constant in acid concentration for periods of at least two hours or more.

Foster and Lambert,[8] on the basis of experiments made on Pawlow dogs, report data which indicate that the acidity of the juice is not constant, but varies from hour to hour. They assert that "early in the digestive period the content of chlorin in the juice is higher than toward the end of digestion." Among other data, they submit that given in Table 2.

TABLE 2.—ACIDITY VALUES GIVEN BY FOSTER AND LAMBERT

Hour	Hydrochloric Acid Per Cent.
First	0.56
Second	0.52
Third	0.44
Fourth	0.31
Fifth	0.22

Foster and Lambert say, "If the statement of Pawlow relative to the constancy of acid is correct, the gastric secretion would form an exception to present ideas of glandular activity."

EXPERIMENT AND COMMENT

In the course of the investigations on the gastric acidity which have been under way in this laboratory for some time, it was noted that there were many individuals, both normal and pathologic so far as the gastric function was concerned, whose gastric juice was rather constant in its acid concentration for considerable periods of time. The data from these cases are submitted at this time as evidence favoring the contention of Pawlow which we have already mentioned. The samples of juice were removed for analysis by means of the Rehfuss tube,[9] which has been used in the investigations previously reported from this laboratory.[10] The following cases have been selected inasmuch as they demonstrate forcibly the tendency of the gastric secretion, after it reaches a certain equilibrium, to be poured out in a more or less constant acid concentration. In the beginning of the curve other forces come into play: (1) the passage of the material through the alkaline mucosa; (2) the union of the alkaline pyloric secretion with the acid fundal secretion; (3) the fixation or neutralization of the acid by the ingested material, and (4) probably the decreased velocity of the formation of the acid and the consequent greater neutralization by the mucosa. When all forces affording a stimulus to secretion are at work this affords a complete evacuation of the glands and a more representative secretion. The curve naturally drops toward the end of digestion, owing (1) to the lack of continued stimuli and (2) possibly to the formation of certain inhibitory or secretory moderator substances such as peptone. It can therefore be understood that during the process of digestion more or less fixation of available acid occurs, giving us a curve which we naturally encounter in normal cases. In the absence of this factor or in the presence of an excessive secretion, the outpouring of juice is of surprisingly constant acid concentration, and, in the absence of some substances which are capable of combining with the acid, remarkably constant in its physical and chemical characteristics. This is particularly marked in the so-called "continued secretion" which we have indicated as following certain types of digestive curves and in the hypersecretion which is encountered. The irregularities in the beginning of the curve and particularly the psychic phase can be explained on the basis of the irregular stimuli which enter into play at that particular moment.

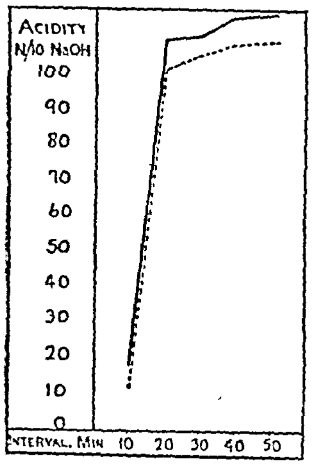

Chart 1.—L., after the administration of 500 c.c. tap water. Solid line, total acidity; broken line, free acid.

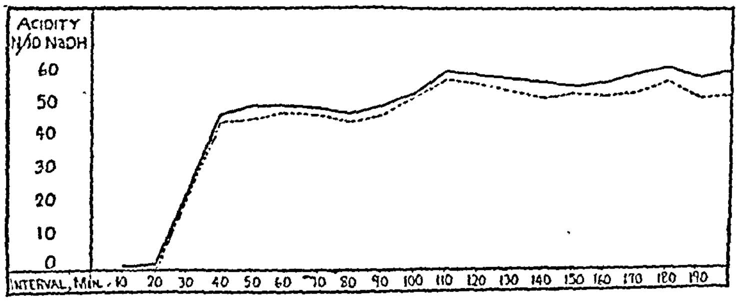

Chart 2.—H., "continued" secretion after the administration of 50 c.c. water at 50 C. Solid line, total acidity; broken line, free hydrochloric acid.

We believe that this constant acidity or the "average" acidity with slight variations in health is always to be found within certain limits, but may be in the absence of combining or neutralizing substances of comparatively high concentration. In disease every variation is encountered which must be interpreted by a thorough study of all the phenomena attending the outpouring of the secretion.

The following experiments are reported in detail because as far as we know they constitute the first evidence (direct) of the outpouring in the human subject of a secretion of constant acid concentration:

Experiment 1.—In a young student, aged 28, an excessive meat eater who smokes cigarets excessively, the figures given in Table 3 were obtained on the empty stomach in response to the introduction of 500 c.c. of cool tap-water.[11] Besides indicating the rapid exit of water from the stomach, the figures show that the character of the juice was remarkably constant in its acid content and that the outpouring of the liquid was unchanged until the termination of the test (Chart 1).

Experiment 2.—In an experiment on Mr. H., a person to all intents and purposes in perfectly normal health, there was an extraordinary continued secretion which lasted for several hours in response to the administration of 50 c.c. of distilled water at 50 C. (122 F.).[11]

TABLE 3.—FINDINGS IN EXPERIMENT 1

No.	Time, Minutes	Total Acidity	Free Acid
1	10	19.0	16.5
2	20	111.5	103.0
3	30	112.5	107.5
4	40	118.5	110.0
5	50	119.5	111.5

TABLE 4.—FINDINGS IN EXPERIMENT 2

No.	Time, Minutes	Total Acidity	Free Acid
1	10	1.5	0.
2	20	2.0	0.
3	30	23.0	21.0
4	40	47.0	45.0
5	50	50.5	46.0
6	60	50.0	48.0
7	70	49.0	47.0
8	80	47.5	45.5
9	90	49.5	47.0
10	100	54.5	53.0
11	110	61.5	58.5
12	120	59.0	57.0
13	140	57.0	52.5
14	150	56.0	54.5
15	160	57.0	53.5
16	170	60.0	54.5
17	180	62.5	58.0
18	190	59.0	53.5
19	200	61.0	53.5

The curve (Chart 2) shows a remarkable constancy with slight rhythmic fluctuations within very narrow limits. Many similar curves were obtained in normal individuals under the influence of varying stimuli, all of which tend to reach a certain level and then fluctuate within very narrow limits.

Experiment 3.—A medical student (Mr. F.) who smokes excessively has never been troubled with any gastro-intestinal disturbance. Lavage of the stomach was followed by the administration of 100 c.c. of water.[11]

TABLE 5.—FINDINGS IN EXPERIMENT 3

No.	Time, Minutes	Total Acidity	Free Acid
1	10	22.5	20.0
2	20	33.5	31.5
3	30	45.5	44.0

15	230	87.0	82.0
16	240	97.0	87.0
17	250	98.5	92.0

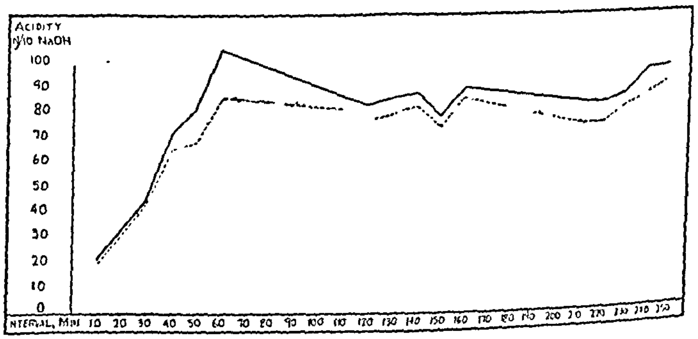

Chart 3.—F., 100 c.c. water after lavage. "Continued" secretion, four hours and ten minutes in duration. Solid line, total acidity; broken line, free hydrochloric acid.

The curve (Chart 3) likewise emphasizes the tendency toward a secretion of constant acid concentration. We have many curves similar to this, indicating that normally after the secretion is fully established, it has a strong tendency to become constant.

---

[11] Bergeim, Rehfuss and Hawk: Jour. Biol. Chem., to be published.

From these frankly normal cases, at least normal inasmuch as they were free from all evidence of gastro-intestinal disturbances, let us turn to several which are distinctly pathologic, mostly recruited from the medical wards of the Jefferson Hospital.

EXPERIMENT 4.—Mrs. I. was given an Ewald meal. A study of the curve in Chart 4 shows first that there was slow response with the rather tardy appearance of a secretion of comparatively low acidity. After reaching this point, with slight fluctuations, it remained at that level and within two and one-half hours there was still an appreciable amount of material in the stomach, although further examination revealed nothing. Cytologic examination was likewise negative; no mucus, no occult blood, only impairment of motility which together with the physical examination and the history justified the diagnosis of atony.

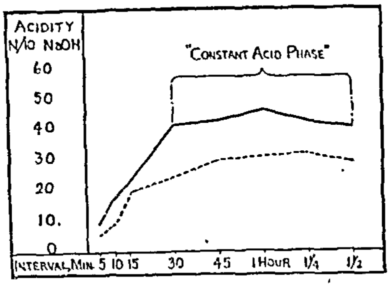

Chart 4.—Mrs. I., Ewald meal. Atony. Solid line, total acidity; broken line, free hydrochloric acid.

EXPERIMENT 5.—The condition of the patient, Miss F., was diagnosed as general visceroptosis, movable right kidney, upper intestinal catarrh and spastic constipation, the whole a part of the typical Stiller syndrome with rather pronounced vagotonic symptoms. Clinically the most pronounced symptoms were those due to atony, the discomfort and eructations following the ingestion of food being due to atony and being completely relieved by measures directed toward that end.

At two and three-quarters hours there was still an appreciable amount of material in the stomach, but examination of various samples, as in the previous case, failed to elicit the slightest sign of inflammation, neoplasm or ulceration.

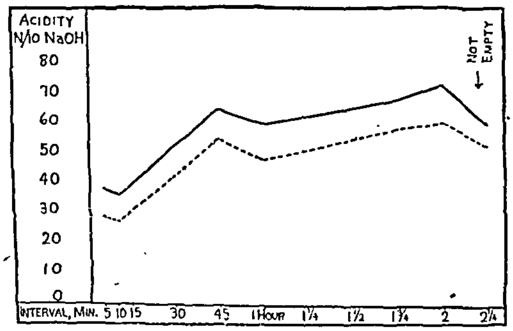

Chart 5.—Miss F., Ewald meal. Vagotonia; gastroptosis; atony. Solid line, total acidity; broken line, free hydrochloric acid.

TABLE 6.—FINDINGS IN EXPERIMENT 4

No.	Time, Minutes	Total Acidity	Free Acid

7	90	66.5	...
8	105	69.5	59.5
9	120	74.0	61.5
10	135	60.5	53.5

EXPERIMENT 6.—This is a definitely pathologic case which illustrates a number of points regarding this study. The individual in question was given an Ewald meal on the empty stomach and the figures given in Table 8 obtained.

TABLE 8.—FINDINGS IN EXPERIMENT 6

No.	Time, Minutes	Total Acidity	Free Acid
1	5	31.8	...
2	10	41.4	...
3	30	30.2	18.0
4	45	30.2	20.0
5	60	35.8	23.3
6	75	38.0	26.7
7	90	43.5	30.0
8	100	43.0	30.3
9	105	51.2	38.8
10	120	50.5	38.0

At this point, the patient began to complain of pain and gnawing, and the figures showed a distinct rise in acidity as follows:

11	135	56.3	44.5
12	150	63.3	52.7

From this point on at 2¾ hours the stomach was empty after a distinct delay, but there followed a pure hypersecretion with average figures of

13	...	76.3	69.8

Careful study of the curve in Chart 6 shows that it is full of interesting data. In the first place the initial figures are high, in fact almost as high as the figures which follow, which average around 40. The high initial figure indicates, what a glance at the specimens shows, that the administration of the meal had been preceded by hypersecretion. The patient therefore had a fasting hypersecretion, which was confirmed by examination of the empty stomach. Then the digestive cycle commences with an outpouring of juice, which is comparatively constant for several hours during which there is no subjective complaint. Although there is a slight rise at one and three-quarters hours, the patient feels comfortable until the two and one-quarter hour interval, when he complains of distinct gnawing and griping. At the same time, it is evident that the stomach is empty and two things are occurring: an outpouring of pure juice which is unsaturated by food, and an increase in the acid concentration of the juice which is being propelled into the duodenum. At intervals he called attention to the cramp-like character of the pain, namely, pylorospasm. This is frequently seen in these cases and indicates the value of this method of examination. It enables us to record graphically the exact changes which are occurring in the stomach at any particular moment, and by the character of digestion record the particular phase in the digestive cycle in which the change is occurring. The pouring of digestive products of the latter part of the meal into the duodenum has given rise, either reflexly or through the action of hormones, to the outpouring of a juice which

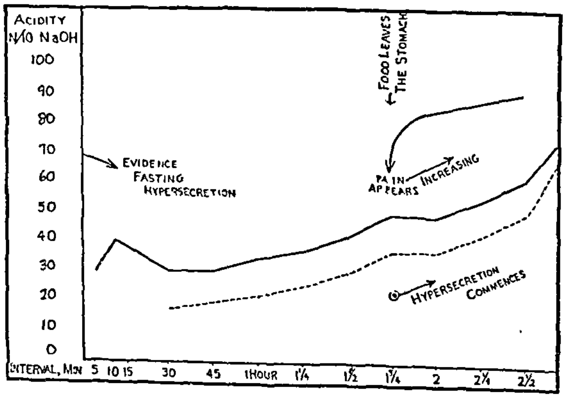

Chart 6.—N., duodenal ulcer, confirmed by operation. Solid line, total acidity; broken line, free hydrochloric acid.

apparently is not of the same character as that observed through the digestive phase, and therefore pathologic for the individual. Another point of interest was found in this case. The examination of the empty stomach revealed a twelve-hour retention (peas, the remains of green vegetables) and the specimens at one and one-half, one and three-quarters and two hours showed definite amounts of free fat. The diagnosis of a stenosing ulcer of the duodenum was made, and an operation was subsequently performed which demonstrated the correctness of the diagnosis.

Experiment 7.—The patient, Miss K. G., complained for several years of severe pain after eating, and on the supposition that an ulcer was present, operation was performed and no ulcer was found. The operation failed completely to relieve her and she continued to complain of the same type of pain with occasional attacks of hyperacidity. The pain was particularly pronounced after she had a bowel movement or anything which decreased intra-abdominal tension and permitted the stomach to sag. The history of this case was more or less typical of ulcer, although the last symptom, as one clinician pointed out, was very suggestive of adhesions. This was substantiated by the intermittent character of the pain often independent of meals. There was, however, sharp pain shortly after the ingestion of food. Accordingly an examination was made of the empty stomach, which showed absolutely no retention but a large very liquid residuum, a fasting hypersecretion. An Ewald meal was then given. The results obtained by fractional examination are recorded in Table 9.

TABLE 9.—FINDINGS IN EXPERIMENT 7

No.	Time, Minutes	Total Acidity	Free Acid
1	20	40.7	18.5
2	30	47.0	....
3	45	50.3	25.6
4	60	48.2	25.9
5	75	43.5	25.0
6	90	42.7	24.3
7	105	44.9	25.7
8	120	48.4	28.5

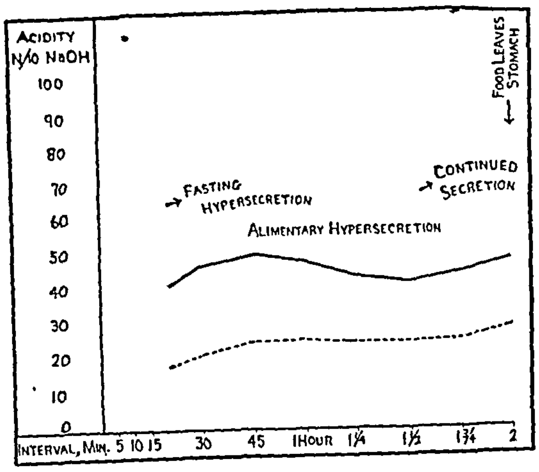

Chart 7.—Miss G., gastric adhesions, confirmed by operation. Notice continued high acidity. Solid line, total acidity; broken line, free hydrochloric acid.

Digestion was over in normal time, and there were no retention, no mucus, no bacteria, no occult blood, in fact nothing unusual about the specimens except the alimentary and continued hypersecretion, there being an exaggerated quantity of juice poured out in every phase of digestion. One point is significant: The gastric curve (Chart 7) is almost a straight line, there being no rise from the abscissa, and with the exception of the first figure, which is but slightly lower than the others owing to temporary saturation by food, the juice is practically of constant acid concentration. This curve is always pathologic and never seen in normal cases. In this case, examination of the stools, cytologic examination of the gastric contents and a study of the albumin content were all against the possibility of ulcer. We could find nothing in the curve or the specimens to suggest ulcer except the obvious hypersecretion suggestive of irritation. Roentgen findings indicated a spastic hour-glass contraction with ulcer on the lesser curvature. We would willingly believe this, but the spastic hour glass should also be accompanied by pylorospasm and delayed motility, particularly with gastric ulcer, evidence of which we could not find. In summing up our conclusions, we suggested ulcer, pylorospasm, possibly a fissure of the pylorus, but in all probability adhesions. Operation was subsequently performed and the only finding was adhesions, causing a transverse constriction of the organ. This case served to intensify the feeling that negative cytologic, chemical and occult blood findings in the presence of hyperacidity and hypersecretion indicate usually an extrinsic cause. The case shows well the pouring out of juice of a constant acid concentration.

Lack of space prevents us from enumerating a number of cases which we have collected after the administration of various stimuli, the Ewald meal, water, etc., which seem to indicate that after the phenomena of initial neutralization and fixation, there is apparently an equilibrium in the factors which bring about the production of acid, and the juice is very constant in its acid concentration. This is particularly the case in hypersecretion and in the normal "continued" secretion cases in which in the absence of substances which are capable of neutralizing the acidity is often remarkably constant. This is particularly the case in the second or chemical phase of the gastric cycle in contradistinction to the initial or psychic phase, which may be more erratic.

CONCLUSIONS

1. By means of the fractional method, we have been able to demonstrate directly evidence of the secretion of a gastric juice of constant acidity in the human stomach.

2. This has been demonstrated in a large number of cases both normal and pathologic.

3. The low acid figures obtained at the beginning of the ordinary curve are explained by: (*a*) the lessened velocity in the formation of acid during the beginning of digestion (Pawlow); (*b*) the partial neutralization of the newly formed acid by the mucosa (Pawlow), and (*c*) the neutralization and fixation of the acid by the proteins of the bread. The lessening in acid figures toward the end of digestion is probably explained in those cases in which that phenomenon occurs and to (*a*) the lessened acid formation incident to the accumulation of inhibitory and sedative substances which tend to lessen acid formation, together with (*b*) a partial neutralization by the food of the acid already formed.

4. A clear exposition of constant acidity is best seen in those cases of "continued" secretion which we have pointed out in normal individuals and in many cases of hypersecretion in which, in the absence of definite material on which acid fixation or neutralization can occur, the acidity remains constant over long periods of time.

5. Pathologic deviations in this "constant" acidity can be noted and are often accompanied by subjective symptoms.

6. This is the first direct demonstration in the human subject in favor of Pawlow's theory of the secretion of a juice of constant acid concentration.

We wish to thank Dr. Olaf Bergeim and Prof. C. C. Fowler for assistance rendered.

Interdependence of Rural and City Health.—Disease is communal. The health of the city is dependent upon the health of the country. A large part of the disease in the cities is brought in from the country.—William De Kleine, in *Pulbic Health*, published by Michigan State Board of Health.

THE PREVALENCE OF OCCUPATIONAL FACTORS IN DISEASE, AND SUGGESTIONS FOR THEIR ELIMINATION *

E. R. HAYHURST, A.M., M.D.
Director, Division of Occupational Diseases, Ohio State Board of Health
COLUMBUS, OHIO

The purpose of this paper is, first, to point out the socially wasteful practice of administering daily to person after person for the same types of morbidity, due to the same causes, and, secondly, to emphasize a much neglected sphere of etiology, the proper conception of which is contained in the term "industrial relations."

The research summarizes a study of (1) U. S. Census Mortality Statistics of Occupations; (2) 65,000 dispensary records and many hundreds of cases personally seen during a two-year period at Rush Medical College (Central Free Dispensary); and (3) the medical portion of 27,887 cases in which the patients received treatment in Cook County Hospital during the year 1913.

1. Attention is first directed to an arrangement of mortality statistics somewhat different from forms customarily shown. An analysis of the mortality statistics of 210,507 persons engaged in 140 occupations in the registration area of the United States exhibits the percentages for the census year 1909 (the only year in which complete tables were published), given in Table 1.

TABLE 1.—MORTALITY AMONG OCCUPIED MALES*

	Those in Agricultural Pursuits. Percentage of All Deaths	Those in 131 Trades and Callings. Percentage of All Deaths
Deaths from *preventable* causes (6/7 are diseases)†	27.4	43.0
Deaths from *degenerative* diseases (under 70 years of age)‡	26.5	31.2
Total deaths after 70 years of age	35.9	13.4

* "Occupied males" include professional callings, officials and proprietors, those engaged in domestic and personal services as well as *those we ordinarily term real workers, namely, those* in trade and transportation, manufacturing and mechanical pursuits, miners, quarrymen, etc., composing a total of 140 chief occupations—including those engaged in nine agricultural pursuits.

† "Deaths from preventable causes" include typhoid fever, pulmonary tuberculosis, pneumonia (under 70 years), alcohol, lead poisoning, other occupational poisonings, suicide, accidental poisonings, accidents and injuries, rheumatism, bronchitis, pleurisy and hernia—for the last four, only such deaths as have occurred under 70 years are included.

‡ "Deaths from degenerative diseases" include cancer, diabetes, apoplexy, heart disease, "other circulatory diseases" (4,858) asthma, cirrhosis of the liver, "other liver diseases" (880), and Bright's disease. There remain in the census classification 27,105 deaths from peritonitis, appendicitis, "other respiratory, digestive, nervous" and "all other causes," a large percentage of which were also undoubtedly preventable or prematurely degenerative, but which are not taken into consideration in the classification given above.

From this we see a marked difference in the prevalence of certain wasteful death causes between the two classes compared. We also note that the agriculturist stands a one-in-three chance of reaching old age (70 years), while the others' probability is but little better than one in eight. None can fail to grasp the significance of this table. To disclaim the importance of these figures on the basis of incorrect diagnoses and uncertainty of occupations is unjust. The fact that only the registration area is included, and the recency of the reports answer the first point. As to the second feature. Wilbur[1] has shown that where another or previous occupation could have been a factor, it amounts to less than 1 per cent., which is less than ordinary errors of transcription.

2. Before proceeding farther it is necessary to explain one or two terms. *Industrial health-hazards* may be defined as working conditions which, while they may not impair the more resistant worker until after a prolonged period, produce morbid conditions in the average worker, and tend ultimately to create preventable and degenerative diseases in all persons so subjected. The hazards, arranged schematically in order the better to remember them, are (1) dust, (2) dampness, (3) darkness, (4) devitalized air, including motionless and vitiated air, (5) heat, (6) cold, (7) fatigue, (8) inactivity, (9) compressed air, (10) infections, (11) poisons and (12) industrial *stimulantism*—the latter a common condition created by the belief among many workers that alcohol, strong coffee, etc., limit or counteract the effects of dust, poisons and other hazards; it is also promoted by dirty, disordered and depressing surroundings and the absence of proper thirst-assuaging facilities at the workplace. It is understood that each of the above-named hazards stands for a class of component hazards.[2]

Among 65,000 different applicants at Rush Medical College (Central Free Dispensary) there were 15,475 persons with definite trades. Professional persons, laborers, housewives and nondescripts were excluded in summarizing. Of this number 10,370 had afflictions deemed not occupational or controversially so, and were also excluded; such were venereal, surgical and acute infectious diseases; sexual, senile and certain skin, ocular (including refractive errors), ear, nose, throat and some nervous diseases. Certain trade tendencies could be noted in many of these; a good part of the surgical cases were strictly occupational. The balance, or 5,105 tradespersons, or about one-third the total number of tradespersons, worked at occupations having definite health-hazards, and had afflictions which such hazards were producing and definitely promoting. Such circumstances would render them applicants for industrial compensation for occupational diseases according to many foreign provisions[3]—"the diseases (scheduled) shall be deemed to have been due to the nature of that employment unless the contrary is proved"—the burden of proof lying on the employer, who has to show that the worker has not been subjected to work hazards which could produce the disease in question.

Among 2,500 consecutive applicants at the Central Free Dispensary Branch of the Chicago Tuberculosis Institute were 875 tradespersons engaged in occupations surrounded with definite and well-known health-hazards. Of this number 615 were found to be tuberculous, 125 were not positively diagnosed and the balance were not suffering from tuberculosis. Of 368 patients who were intelligent and answered questions,

* Results of a study conducted at the Central Free Dispensary (Rush Medical College) and Cook County Hospital, Chicago, under the Occupational Disease Fellowship of the Otho S. A. Sprague Institute for Infectious Diseases.

[1] Wilbur, Cressy L.: "Vital Statistics in the United States," Am. Jour. Pub. Health, December, 1913, p. 1258.

[2] The Ohio State Board of Health, in the survey of industrial hygiene and occupational diseases which it is now conducting, uses, for workplace investigations, a card 4½x7 in. on which is logically arranged a *complete list* of the usual health-hazards of industry. By a simple code each is opinionated as "good," "fair" or "bad," as inspection reveals.

[3] See "Compensation for Industrial Diseases," by E. T. H. Lawes, 1909, Stevens and Sons, London, 306 pp. Also, "Order Extending the Workmen's Compensation Act," Great Britain and Ireland, Bull. Int. Labour Office, 1914, ix, Nos. 1, 2, pp. 23-24. Also, "Compensation for Occupational Diseases," Ontario, Canada, U. S. P. H. Reports, Aug. 21, 1914, xxix, No. 34, p. 2176.

259 made complaints of working conditions involving dust, light, dampness and ventilation. Their statements were not taken as to the more insidious hazards such as poisons, fatigue effects, liability to communicable diseases, temperature exposures, and industrial alcoholism.

3. In Cook County Hospital in the year 1913 there were 11,022 adult medical cases. Of this number, at least 2,866, or about 27 per cent., were persons engaged in definite trades having well-known health-hazards and were suffering with afflictions which were induced or promoted by such hazards. None of these, so far as we know, received compensation or even condolence from the sources responsible, nor, indeed, were their cases investigated by an executive branch of the government.[4]

It might be considered advisable to give a division of all of these 11,022 persons by "occupations" and by diseases. This was attempted, but it suffices to say that a large majority of this class of "down and out" patients have no regular occupations, and that, also, the term "occupation" as used in a charitable institution of this sort is capable of such loose construction that, unless each case is painstakingly examined, records and casual statements more often mislead than direct. The term "laborer," for instance, was found to apply to practically all occupations.

In the hospital diagnoses of these 11,022 medical cases, one finds none classified under the head of "occupational," or "industrial" diseases. Turning next, however, to the prominent poisons, and running them through, the records disclose cases charged to industry as given in Table 2.

TABLE 2.—CASES OF POISONING CHARGED TO INDUSTRY

	No. of Patients
Lead poisoning	47
Arsenic poisoning	3
Wood alcohol poisoning	1

But if such a search is extended to *diseases which might be occupational,* such as dermatitis, eczema, bronchitis, tuberculosis, heat-exhaustion, tetanus, flatfoot, lumbago, rheumatism, constipation, gastritis, pancreatitis, appendicitis, nephritis, neuritis, and particularly neurasthenia, one finds many comments on the history sheets savoring of occupational etiology. In fact, after such a search one comes to the conclusion that almost any medical complaint may be occupational, or at least may have in its etiology an important occupational factor.

As limited in number as are the *lead poisoning cases* noted, they are more frequent in occurrence than in the year 1910 in the same hospital. In spite of all legislation which followed the report of the investigation by the Illinois Commission on Occupational Diseases in the year 1910, they have still continued to come[5] and in several instances from the same identical workplaces.

An analysis of the principal symptoms given on the history records and used for arriving at a diagnosis in the cases of plumbism is given in Table 3. It is based on forty-six of the cases, as one patient absconded from the hospital before clinical features could be determined.

TABLE 3.—PRINCIPAL SYMPTOMS IN FORTY-SIX CASES O PLUMBISM

	Per Cent.		Per Cent
Colic	98	Basophilic degeneration	4
Constipation	91	Headache	42
Lead line	80	Albumin and casts	2
Vomiting	78	Multiple neuritis	27
High blood-pressure*	75	Wrist drop†	1

* Determined in only 16 cases. In no case was it less than 125 mm. Hg, but in 12 cases it was more than 100 plus the age in years.

† The detection of lead paresis, preceding paralysis, can be made early, in the case of the arms, by the use of the hand dynamometer (Hayhurst, E. R.: Critical Examination of One Hundred Painters for Evidences of Lead Poisoning, Am. Jour. Med. Sc., 1914, cxlvii, 788).

The high percentage of lead lines shows quite conclusively that many cases without lead lines were not diagnosed as plumbism, since this sign is certainly not present in over one-third of even acute cases. Most lead workers are instructed and have learned to take "salts" regularly and as a result do not suffer much from colic, constipation, vomiting and headache, but they do suffer nevertheless from chronic plumbism as is shown by weakened neuromuscular function, blood-pressure determinations, facial pallor, impaired nutrition, affected kidneys, hardened arteries and fundus oculi examinations.

Analyses show that a total of 530 patients were engaged in processes which exposed them to lead in its various forms. As mentioned above, but forty-seven patients were industrially poisoned in the scrutiny of the histories of these cases. Among the balance we cite below the details of ten selected cases. Space alone limits the publishing of many times this number. I do not question the diagnoses made, necessarily, but wish to comment on their incompleteness. (The hospital diagnosis is given first, with civil statistics, and some of the symptoms; then the results, in briefest form, of our own investigations in connection with each case.)

Case 1.—*Aortic Aneurysm.*—Laborer, aged 52, U. S., signs of aneurysm, with symptoms of angina pectoris. Symptoms beginning four months previously. Found to have worked for the past three years in a lead factory, inordinately exposed to lead. This case ended fatally, presumably by rupture of the aneurysm. Four and one-half months in the hospital.

Case 2.—*Alcoholic Neuritis and Nephritis.*—Painter (general), aged 40, U. S. Found to have had an attack of acute plumbism two months before, with wrist-drop. Had his first attack twelve years before.

Case 3.—*Musculospiral Paralysis and Multiple Neuritis.*—Laborer, aged 32, Pole, double wrist-drop, blue line, basophilic degeneration. Found to be a lead worker. Later sued his employers for his condition. How much the hospital diagnosis will help or hinder his suit is left to the reader to conjecture.

Case 4.—*Arteriosclerosis.*—Painter (general), aged 54, U. S. History of several lead-poisoning attacks and in the hospital but a few months before for "lumbago."

Case 5.—*Constipation.*—"Iron molder"—such was his regular trade, but he worked in a paint factory for one week, putting paint in cans—aged 38, Pole; symptoms acute. Stated that the work-room was filled with dry paint dust, and that masks were "more or less" constantly worn.

Case 6.—*Pus Appendix,* gangrenous (diagnosis made by abdominal section). Russian, aged 31. Within the past year a farmer in Russia. Sick for past four months. Found to be a white lead molder, and made great complaint of the amount of lead fumes and dust he was compelled to breathe. Place of employment the same from which four other cases of lead poisoning had come to this one hospital within the period of our observations.

Case 7.—*Chronic Rheumatism and Acute Uremia.* Painter (general), aged 60, Irish. Sick for past two months. Entered hospital in semicomatose condition with convulsions. Found to have had lead colic as far back as twenty years previous.

---

[4] In this connection we may say that the powers of the state factory inspection department, limited as they are to the reports of factory physicians only and then to a certain few *poisonous* industries, do not permit of aggressive investigations of this sort.

[5] See Bull. Ill. State Depart. of Fact. Inspect., October, 1913, and April, 1914, i, 1 and 2.

Case 8.—*Catarrhal Jaundice.*—Laborer, aged 28, Greek. Sick twenty-one days—colic. Found to be a lead smelterer, and from the same place where several other positive cases of lead poisoning occurred, several of the patients entering this hospital within the past year. The firm is an old offender.

Case 9.—*Neurasthenia.*—Painter, aged 42, Hungarian. Complaint, abdominal pain. Had similar attacks off and on for the past four years. Found to be a passenger car painter, and complained of breathing paint dust. There have been many cases of lead poisoning reported, both at this hospital and elsewhere, among his fellow workers.

Case 10.—*Paratyphoid Fever.*—Battery assembler, aged 23, Lithuanian; abdominal colic; blue line. Found to work in a storage battery factory exposed to much lead dust. Also had all symptoms of lead colic eight months previous.

This series illustrates how easy it is for primarily occupationally diseased patients to be lost sight of in terminal complications; the necessity of going deeply into the exact occupational risks which the patient has endured, and the lack of significance of the term "laborer." Furthermore, these cases emphasize very well the social waste in continuing to treat, and failing to diagnose etiologically cases which keep coming from the same sources, trades and callings year after year.

Industrial *arsenic* poisoning is not frequent in Chicago, yet the three cases noted above were hardly one-fourth of the total in this one hospital; another ten cases (all acute), which we could discover, were termed "dermatitis," "eczema" and "acute gastritis." In this connection it is well to state that in several instances these patients gave their previous regular occupations, such as "boilermaker," "electrician" and "jeweler," instead of mentioning their recent arsenic-industry employment, when questioned by the hospital entry clerks.

The three diseases given in Table 4 were correlated with occupations of the patients; the figures give the numbers which were in whole or in part occupational in character.

TABLE 4.—OCCUPATIONAL CASES IN THREE DISEASES

	No. of Patients
Chronic nephritis	265
Rheumatism (various forms)	417
Organic heart disease	333

In the case of the latter disease it is well to mention the efforts now being made in New York and at Cincinnati to select proper forms of work for such patients after discharge, in order to prevent occurrence and recurrence of non-compensation and consequent return to hospitals.

No cases were recorded of *pneumonoconiosis,* or of its various forms, as *siderosis, chalicosis, aluminosis,* etc., although there were a total of 134 cases of *chronic bronchitis* without efforts at etiologic diagnosis.

There were recorded 229 cases of *arteriosclerosis.* Unfortunately an idea of the extent to which fatigue-substances, heat-toxins and extrinsic poisons of industrial origin may have entered into this class of cases can rarely be gained from present-day histories anywhere; hence any idea of using the information for shutting off the oncome of such cases is at once precluded. They are all charged apparently to the account of moral hazards, or disease misfortunes.

There were 156 cases of *neuritis* of various types. While the preponderance of alcoholism and drugging as causal may be admitted, each should be searched for the likelihood of industrial poisoning, both extrinsic and intrinsic. For example, multiple neuritis occurs at a given rate among all alcoholics, but among those exposed to lead it is unusually common. We did not find time to go into these.

There were 157 cases of *neurasthenia* for which no other cause could be found than exhaustion, and we know that every effort was made by diagnosticians to keep this number minimal. Why should not the cause of such exhaustion be inquired into with the idea of naming it etiologically, and, if industrial, as it probably is in 90 per cent. of the cases, of recording it as *occupational neurasthenia?* If each such case were looked at from this point of view, corrective agencies would have a case to investigate.

There were twenty-eight cases of pes planus, fifteen cases of tetanus, and numerous cases of skin disease, heat exhaustion, neuralgia, uremia, etc. Here and there was a mention of work etiology, but the mention was productive of nothing. In fact, it was lost sight of entirely through the absence of a heading in the filing system under which to place "occupational complaints." It is largely on this account that so few occupational diseases can be found in institutional records anywhere (they are nearly all alike in this respect) when one intuitively feels they are omnipresent, especially if any field work has been done in industrial health-hazards.[6]

During the course of the year 1913, there were in the hospital *2,230 adult cases of tuberculosis* (I understand that not over 50 of these were "repeats"), 1,800 males and 430 females. One may safely say that practically none of these had active tuberculosis at the age of 14 years! The question is, Why and how have they acquired it since? How many of them would have it now had they lived an agrarian existence, for instance? The predisposing causes of their tuberculosis may be placed under three heads: (1) moral hazards, (2) domestic or housing hazards, and (3) industrial hazards. These three factors operating, perhaps, in unison have caused either a reawakening of latent childhood infection, or have invited environmental infection. Without disregarding the importance of the first two hazards, I am of the opinion that the importance of industrial hazards has been greatly underestimated in almost every case, and that it is useless to fight tuberculosis unless the daily eight to twelve hours vocation be investigated and supervised. The so-called "occupations" under which these 2,230 tuberculous persons were registered give practically no information of value. For this, it would be necessary to individualize cases. The records show one thing which is certain, however—that *they keep coming,* and very largely *from the same environments.* One important analysis shows that there was a total of 672 medical patients in the hospital engaged in dusty trades, of whom 284, or 38 per cent., were tuberculous. This is almost double the general tuberculosis rate among the medical (adult) cases in the hospital (20.2 per cent.). For "laborers," as a class, the percentage of tuberculosis was 23.3 per cent.

A principal feature in all these cases is to determine exactly the occupations. The principal result should be an etiologic diagnosis as far as possible, including the use of qualifying terms such as "bronchitis, occupational," "neuritis, chiefly occupational,"

---

[6] Several excellent text-books have recently appeared on occupational diseases and industrial or vocational hygiene which discuss the various hazards of each calling.

"aortic aneurysm, probably occupational," "nephritis —alcoholic and lead," etc. This is similar to uses elsewhere, as seen in such descriptive terms as *puerperal* sepsis, *tuberculous* pneumonia, *typhoid* fever and diabetes *mellitus*.

It must not be forgotten that patients themselves are densely ignorant of what constitute health-hazards; that they calmly accept them as a matter of course, and unworthy of notice; that the competition for work is great; and (one comes to realize) so much greater than everything else is *the innate desire in man to work*—a desire which, in the normal man, equals his appetite and seeks to be satisfied in spite of all conditions.

SUGGESTIONS FOR THE SOLUTION OF THE PROBLEM OF OCCUPATIONAL DISEASES

The health-hazards of industry which cannot be feasibly removed are insignificant in number.[7] The best proof is the fact that certain establishments engaged in the industries and processes in question have circumvented such hazards, and invariably to the improvement of production, as well as labor attitude and relations.

1. First, there is needed a nomenclature to designate properly what is meant by "occupation." No one word will do this. The word "occupation" as used in medical parlance, hospitals, institutions, anti-tuberculosis society records, etc., should be abolished absolutely. A little study of some of the application blanks of insurance companies, particularly those carrying sickness insurance, offers many suggestions to framers of history sheets, social statistics, nurses' records, etc. After considerable study, and several years of field and statistical experience with this question, we have evolved and are using a scheme to take the place of the word "occupation" as outlined in Table 5.

TABLE 5.—SCHEME TO TAKE THE PLACE OF THE WORD "OCCUPATION"

INDUSTRIAL RELATIONS
(AS STATED BY THE PATIENT)

	Present	*Past*	*Previous (to Past)**
1. Name of employer			
2. Address of employer			
3. Business of employer			
4. Calendar years worked here..			
5. Department(s) worked in....			
6. Particular process(es) engaged in			
7. Health-hazards† exposed to...			

* For acute afflictions it is not necessary to go back beyond a few days or weeks, perhaps. For recurrent afflictions one should go back months or years. For chronic afflictions it is necessary to go back preferably five years or more. It is not to be expected that the busy entry clerk will fill out this record. It should be the duty of the history taker, oftentimes with the aid of an interpreter, and, if significant, even with outside assistance.

† Question "7" should be answered whenever there is any possible relationship between the patient's affliction and his industrial relations.

This is not dissimilar to what is ordinarily inquired into by the average insurance company. The question at once arises, Should not social and charitable institutions demand just as thorough an investigation of industrial relations as a sickness insurance company? Certainly the taxpayers of a community have a right to demand as much.

2. It is a serious handicap to many interests that there is to-day no logical classification of occupations in existence. To different persons the same term conveys quite dissimilar intelligence. With the information obtained from the use of the blank form given in Table 5, a *logical classification of occupations* may be attempted. While the names and addresses of employers are not necessary for the classification in question, they should be required on all institutional case-records as legitimate information pertinent to the care and supervision of the case. With the facts secured by Answers 3, 5 and 6, any given type of worker and all of his kind may be descriptively and distinctively classified. A scheme to classify occupations must collate "industry," "business department" and "trade process." It therefore requires three descriptive terms to do this. "Industry" must be considered, because, for example, a fireman at a zinc smelter-works is subject to considerably different hazards from those of a fireman in the boiler room of a public building; "business department," because, for example, a cook with a railway construction gang has considerably different hazards from those of a cook on a railway dining-car, etc. Let us apply this principle to a heterogeneous collection of workers (Table 6).

TABLE 6.—THE COMPLETE STATEMENT FOR "OCCUPATION"

Industry	*Business Dept.*	*Trade Process*
Pottery	Clay shop	Jiggerman
Pottery	Glaze room	*Dipper's helper*
Vehicle	Painting	Painter and sander
Agricultural implements	Painting	Dipping machine laborer
Iron and steel	Butt mill	Furnaceman
Brass	Foundry	Furnaceman
Iron foundry	Foundry	Laborer
General	Nondescript	Laborer

In this way it is possible to classify any one's trade or calling exactly. As in the case of "iron foundry," redundancies seemingly occur, but these are only apparent, for all the information obtained is necessary to exactly identify each worker's industrial application and environment.

It is not necessary for two persons to describe the terms exactly alike for a given case; nor, in the case of the same activities at two separate places, is it necessary to have descriptions identical, word for word. The information given under the three headings will invariably convey intelligence enough to enable a third person to comprehend fully just what is meant. The statistician is at liberty, furthermore, to enlarge the groups so as to come under the usual general industrial headings: agriculture, professional, personal service, trade and transportation, manufacturing and mechanical pursuits, and miscellaneous.

3. With the occupation definitely known and the health-hazards recorded, the weight of these in the affliction at hand can be estimated. The next step is to *investigate and verify* the patient's statements. Right here is where our system of social service fails. It is at present nobody's official business to attend to this. This function should constitute a part of the *statutory business of the community health department* whose findings, when positive, with recommendations and suggestions, should be given over to the proper (state) executive department. It should also become a corollary obligation on this health body to lead in the hygienic education of the workers, and to some extent of the employers, by drawing up rules and regulations to be observed by both of them and to be posted in workplaces as health-placards. This last function should not be hampered by having to wait for preparatory legislation aimed at each line of industry, as is now the usual manner of remedying such conditions. This power is just as much the rightful function of the health body as any of the offices

---

[7] See Symposium on Ventilation, Jour. Indust. and Eng. Chem., March, 1914.

it now performs. *This power should be legalized and made mandatory on the health body.*

4. The enforcement of such regulations should depend, in the end, on the *compensation principle,* by which the employer will soon undertake to supervise his own plant, quite independent of the state's enforcement, as well as the health of his workers, both in and beyond the workplace, the latter on the now accepted theory that the employer has a right to demand "his money value for his expenditure for labor." Physical supervision, medical examination of employees, and a better selection of workers for the job will be the first effects of this system, while workers whose sicknesses are the results of moral or domestic hazards will soon be educated into line, or eliminated from industry. As industrial relations usually determine home conditions and habits, it would appear rational at all times to make an attack on delinquent social conditions at the place of employment.

SUMMARY

As a result of considerable study of hospital and dispensary cases and records, of vital statistics, and of field investigations, we reach the following conclusions:

1. Occupied persons, other than agriculturists, suffer an enormous mortality (figures show 74 per cent.) from well-recognized preventable and prematurely degenerative diseases.

2. Occupational diseases exist because industrial health-hazards exist. Responsible employers do not realize the existence of either, while treating agencies take little cognizance of employments.

3. From one-fourth to one-third of the medical afflictions of tradespersons are due in whole, or in great part, to industrial health-hazards.

4. In institutions, the vast majority of industrial diseases are lost sight of through failure to recognize properly the industrial relations of the patients, to make etiologic diagnoses, and to classify properly in subsequent filing.

5. Specific occupational diseases, such as lead poisoning, are not recognized in more than one out of three or four instances, more especially the chronic cases.

6. Present-day institutional records are of value only in showing the enormous numbers of representatives of groups of industrial pursuits who are below the physiologic normal, and who seek medical aid for preventable ailments. Such records have little value to the student of economics.

7. A most important first remedy is a proper nomenclature for industrial relations to take the place of the word "occupation." Such a nomenclature is here propounded. The chief feature of this is the introduction of the term "industry-department-process" for the word "occupation." Adoption of this proposed term, furthermore, renders a logical classification of occupations possible. No such classification now exists.

8. The powers and functions of the community health-governing body should be extended to the prompt investigation of all industrial complaints, and to the prompt remedying of them without the necessity of preliminary legislation against certain alleged responsible industries.

9. In spite of the fact that the state in which this study was made has an occupational disease law, workers are still coming into its charitable institutions from the same types of trades, and in some instances, from the same manufacturing establishments, in even greater numbers than at a period three years previous, when the Illinois Commission on Occupational Diseases made its investigation. This, we charge, is most directly due to the non-existence of a correlating body between the hospital and the factory.

10. Too much importance is usually given to alcoholism, with a failure to appreciate that subjection to industrial health-hazards in itself induces and promotes stimulantism.

As a noted health officer has stated, many occupational afflictions might well be made the subject of a grand jury investigation, and others, of a coroner's inquest. The enormity of the public and private sums now spent on preventable sickness and death should induce those who pay the tax to bend every effort to run down these contributory factors and abolish them.

Acknowledgment is made of the valuable assistance rendered by Drs. Pauline R. Kapsa, C. A. Link, Alvin Thompson and F. B. Smith, of Chicago, in the accumulation of statistics and material contained herein.

CLINICAL CLASSIFICATION OF ETHMOIDITIS*

E. M. HOLMES, M.D.
BOSTON

As a result of the efforts of many observers during the past quarter of a century, we have acquired considerable knowledge concerning the inherent and associated pathology of the ethmoid cells. The clinical study of these cells is still of great importance, for by the knowledge thus obtained we are better able to judge of the macroscopic pathologic changes observed by direct inspection and by the aid of endoscopic instruments. Endoscopic examination of the nose enables us to inspect recesses which are otherwise hidden or at best only poorly observed. There is great need of study in this direction, for many of the findings are more positive than can be obtained in any other method. The roentgenogram is an aid which is of much service in some cases of ethmoid disease. It may give a working knowledge of the arrangement and size of the individual cells and it may be of considerable help in demonstrating the coexistence or the absence of associate sinus disease. We have also made considerable progress in our ability through surgical and medical means to relieve local pathologic conditions—those due to extension into adjacent structures, and also those due to reflex nervous impulses. From a clinical point of view there is still need of much research into the pathology and treatment of this region. We are in need of more uniform nomenclature and there must be a better understanding in regard to the best procedures, medical and surgical, for the relief of the various conditions with which we have to deal.

It is important that we do not forget that the ethmoid with the middle turbinate performs two very important functions. The air-spaces within the ethmoid act as non-conductors of heat and cold as well as other irritations, and through this structure the orbit and its contents are protected from the frigid currents of air which are inhaled during cold weather and which without this non-conductive barrier would come into close contact with these delicate structures. The restriction of the superior and middle fossae of the nose by the ethmoid with its middle turbinate and covering of erectile mucous membrane provide for the warming and moistening of the inspired air before it enters the throat and passes into the lower respiratory organs. When for any reason the middle turbinate and lower wall of the ethmoid have to be sacrificed there results a deformity which practically produces all of the ill effects of mouth-breathing. The inspired air is not sufficiently warmed or moistened and there almost always follows a chronic dry pharyngitis and a chronic laryngitis. Frequently the trachea and bronchi suffer in like manner as the upper respiratory organs. These patients almost always suffer from orbital as well as nasal disturbances whenever they are subjected to the influence of cold or dry air or to air contaminated with irritating dust or gases.

---

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

I am devoting considerable space to these preliminary remarks concerning the physiologic functions of the ethmoid and to the resulting disturbances when for any reason this structure has to be sacrificed, as it is of the utmost importance when we take up the study of this subject in the concrete. Were it not for the great importance of this structure, the clinical significance of our study would be reduced to a simple operative procedure. There would be nothing gained by the expenditure of time and energy in trying to differentiate between the infections of the various cells of the ethmoid or of the middle turbinate, for it would be easier to remove all of the turbinate together with the nasal wall and trabeculae of the whole ethmoid. With our present knowledge, the most important thing is to ascertain, so far as possible, the degree and extent of the existing pathologic conditions, to learn of the duration of the disease and whether there have been previous attacks, to consider the inconvenience of the existing ethmoid disease to the patient, the degree of extension into other structures and the inconvenience as well as danger due to this extension. It is likewise of great importance to consider the patient's general condition, his hygienic surroundings, his habits and previous treatment, if any. After having gone over the individual case, unless we are sure that the whole ethmoid structure is beyond repair, I believe it is our duty to make the patient understand that it will give better results in his case to save all the nasal structures possible and tell him that in trying to obtain this final result several operations may be necessary. After this understanding, we should do only what we believe to be essential to accomplish the results and follow this up with suitable treatment, resorting to further operative interference if found necessary. We cannot make this point too strong because it is so easy to be led into extensive radical exenteration; and it is impossible to restore structures once removed or to overcome the symptoms frequently resulting from this extensive loss of tissue. In extensive ethmoid diseases it may be absolutely impossible to stop the progress or to give relief without thorough exenteration. When we are able to prove that we are dealing with such conditions it would be folly to attempt what would ordinarily be conservative treatment. The most thorough exenteration is none too radical and must be advised.

The ethmoid cells are intimately associated and are practically a part of the labyrinth of cells beginning anteriorly with the frontal and ending posteriorly with the sphenoid. Through their drainage they are also more or less intimately associated with the large inferior orbital cell, the maxillary antrum. In dealing with the ethmoid cells—from an etiologic, a diagnostic, a prognostic and a therapeutic point of view—we have to consider carefully the frontal and sphenoid cells and also the maxillary antrum. The symptoms are frequently exaggerated by those arising from a coexisting frontal, sphenoid or maxillary disease, or they may be simulated by disease of these associated areas. Again, disease of the maxillary may be simulated or produced by the discharge of a diseased ethmoid into its cavity.

Irritation of associated nerve filaments, especially the dental, may produce symptoms of pain and sometimes hypersecretion of mucus within the nose which naturally suggests infection and may lead to a wrong diagnosis unless much care is exercised.

Clinically, we see a number of pathologic conditions within the ethmoid. These conditions vary in intensity and produce varying and various degrees of symptoms. These symptoms are not necessarily a guide to the severity of the pathologic process. The anatomy varies considerably and this variance is an important factor in the production of the symptoms and in the progress of the pathologic processes.

Although it is clinically impossible to classify satisfactorily the pathology of the ethmoid, for the purpose of more easily presenting the clinical aspect, we can first divide it into two classes, the purulent and the non-purulent. The purulent may be either acute or chronic. The non-purulent may occur as an acute inflammatory, a chronic inflammatory, a degenerative (polypoid and atrophic), a syphilitic, a tuberculous or a neoplastic. The purulent or non-purulent types may occur independently or may be associated. The acute inflammations are extremely common and are usually associated with attacks of acute general rhinitis. The majority are self-limited. They are often the most difficult to diagnose as the symptoms are frequently the only real guide, and when the drainage is not materially obstructed the symptoms may be so slight that the condition is overlooked. When there is associated purulent secretion which can be observed coming from some of the ostia, the diagnosis is easier and more positive, but more frequently the secretion if excessive is mostly serum and it is practically impossible to state positively from what area it is coming. It spreads out over the mucous membrane of the turbinates and fossae and discharges from the nose anteriorly or into the epipharynx posteriorly.

The symptoms in this condition are usually not severe until some of the channels of escape become blocked by the swollen mucous membrane. When there is a blocking of excessive secretion from the ethmoid cells there arises a sensation of fulness and heaviness within the head and there begins a more or less severe pressing pain which radiates from the eye and often extends into the temple, the parietal, and sometimes into the postauricular areas. All the visible mucous membrane within the nose is usually infected and more or less swollen, as the results of the infective process usually spread over quite an extensive area.

The important objects to accomplish are first to relieve the distressing symptoms and to relieve pressure within the bony encased areas so that normal circulation may be established and the inherent vital forces given a chance to combat these infective elements and restore normal conditions as quickly as possible. The more rapidly and perfectly this takes place, the less liable is there to be a weakened resistance or a chronic termination. Though 70 per cent. or more of the acute inflammatory processes within the ethmoid cells are self-limited and result in cure without any interference, the knowledge that the others are liable to become chronic and may become extremely severe, producing not only local distress but also general infirmity, should make us very careful in studying and treating all the patients who come to our attention. It is important that the general condition of the patient receive immediate and appropriate treatment. The gastrointestinal tract must receive attention and the patient should be protected from exposure and fatigue.

Locally, much can be gained from a diagnostic point of view by a systematic application of cocain about the ostia which naturally drain the various accessory cells. In order to gain positive knowledge, it is advisable to use a very small cotton-tipped applicator saturated with 5 to 10 per cent. cocain solution, and to carry this directly to the anterior portion of the middle fossa under the tip of the middle turbinate. The patient's head should be inclined forward. If after a few minutes the distressing symptoms are relieved we can reasonably assume that the principal cause of the trouble is the anterior portion of the ethmoidal labyrinth or within the frontal sinus. At least the main object of our research, the relief of the pressure and faulty drainage has been obtained, and if this can be maintained our patient is nearly always started on the road to recovery. If this first application gives only slight or no relief, the next application should be made at the posterior end of the middle fossa where the posterior cells are liable to communicate with the nose. After this procedure the floor of the nose can be anesthetized and a thorough endoscopic examination made.

In acute cases in which cocain and epinephrin establish drainage and give relief to the symptoms, the local use of these with the addition of argyrol is usually sufficient to effect a recovery in a comparatively short time. There are cases with acute onset in which we cannot establish drainage and give relief by local application, and more radical interference may be necessary. These cases may be annoying as we realize the great necessity of preventing serious advance and destruction of tissue and the desirability of sacrificing as little of the nasal structure and function as possible.

If the site of the disturbance seems to be in the anterior group of cells, an excision of the extreme anterior portion of the middle turbinate may be advisable and the anterior internal wall of the bulla ethmoidalis may be removed. The temptation is to use the curet extensively within the spongy cells, but this must be resisted until such time as we are reasonably sure that it is absolutely necessary.

Chronic suppurations of the ethmoid vary much in degree and in severity of symptoms. The purulent secretion within the nose is frequently very annoying, and that which flows backward into the epipharynx and into the pharynx may be very distressing when profuse, and extremely disagreeable when it is retained and forms decomposing crusts. The irritation of the mucous membrane within the nasal chambers with the resulting swelling frequently impedes the passage of air. There is often pain over the bridge of the nose or radiating from the nose to the temporal region. There are at times disturbances within the orbit. Frequently the complications within the epipharynx and eustachian tube produce the only severe symptoms. Quite often there is more or less enlargement of the normal cellular spaces because of retention of hypersecretion, and frequently these cells become much distended. This is especially true of the middle turbinate. When the condition is at all advanced, the cystic turbinate obstructs the nasal passage and produces the symptoms due to obstruction. The chronically inflamed ethmoid when subjected to excessive pressure from retained secretion frequently becomes necrotic. If this necrosis happens to break down the cell walls so as to produce good drainage, the process is occasionally self-limited. This is not, however, the general course of events. There usually develops more or less profuse granulation-tissue which tends to retain the secretion, and unless aided by surgery the process slowly advances. In this condition the middle turbinate may become so cystic and enlarged as practically to fill the superior fossa and obscure from our direct or endoscopic inspection the middle and superior fossae of the nose. Pus may be seen in the groove about the turbinate, but it is impossible to determine its original source. Sometimes much can be gained by crushing the turbinate with forceps, as sufficient space may be gained to be able to inspect the middle as well as the superior fossa. When there is sufficient space to obtain a good endoscopic view we can frequently determine the extent and location of the disease. The increased space obtained by reduction of the turbinate may enable direct treatment and a cure may result with little sacrifice of tissue and slight, if any, loss of function. When there is extensive degeneration and necessarily much loss of structure we can hope for relief but not a restoration of a normally functioning nose.

Polypoid formation as well as the hypertrophic inflammatory processes may begin as very circumscribed conditions and without purulent manifestations. Polypoid formation may exist for years and become very extensive without becoming purulent. While examining the nose with the endoscope we not infrequently discover small polypi within the middle fossa under the middle turbinate which have given no symptoms and might cause none until they had become large enough to appear below the turbinate. So far as the ethmoid is concerned, the mucous polyp is practically a malignant manifestation. Unless there is thorough removal of the growth together with the adjacent structure, there is almost sure to be a return of the condition. Little can be expected from a simple snaring of the polypoid mass, and in advanced cases permanent relief can be hoped for only through a radical exenteration of the ethmoid.

Syphilitic disease of the ethmoid may at first appear as a simple acute or a subacute inflammatory process. Later it may give symptoms and show the signs of a purulent ethmoiditis. It is important in all ethmoid disease to consider and estimate, if possible, the possibility of syphilitic infection. When there is a possibility of the ethmoiditis being due to syphilitic extension, surgical interference should never be resorted to until after thorough antisyphilitic medication.

Neoplasms of the ethmoid other than polypi are very rare, and when discovered are frequently beyond eradication. Whether of the sarcomatous or carcinomatous type they are usually friable and very vascular. Any soft vascular tumor within the nose should arouse suspicion and receive immediate attention.

The technic of the various operative procedures is so well known that it has not seemed necessary to consider the subject here. It is also very difficult to deal with this subject in a conservative manner without being misunderstood. In certain cases the most radical procedures are really conservative, and were it not for the importance of the surrounding and associated organs they should be made even more radical. It is so much easier to perform a radical operation than to be obliged to perform perhaps several less thorough ones that inasmuch as the radical measures sacrifice more of the physiologic functions it is our duty to refrain from great sacrifice of tissue unless we are reasonably sure that other so-called conservative measures will not suffice.

PATHOLOGY OF THE ETHMOID LABYRINTH*

G. E. SHAMBAUGH, M.D.
CHICAGO

In this consideration of the pathology of the ethmoid I shall take up only some of the more common pathologic conditions which have come under my own observation and discuss the clinical symptoms by which these conditions can be recognized.

The most frequent pathologic condition involving the ethmoid labyrinth is acute catarrhal ethmoiditis. This develops as a frequent sequel to an acute coryza. The changes in the mucous membrane covering the ethmoid which are characteristic of this condition can often be observed by an examination of the middle meatus where the ethmoid labyrinth comes more or less clearly into view. In these cases, by inspection we can recognize along the under surface of the middle turbinated body, along the unciform process, and along the exposed surface of the bulla ethmoidalis, an edematous-like swelling of the mucous membrane. Occasionally we observe in this acute form of ethmoiditis the formation over the exposed part of the ethmoid of small mucous polypi, which tend to disappear spontaneously on the subsidence of the acute process.

The occurrence of acute catarrhal ethmoiditis can usually be recognized from the symptoms, which are the result chiefly of impaired ventilation and drainage of the ethmoid cells, occasioned by the swelling of the mucous membrane. The patient experiences a characteristic sense of pressure and fulness, or even of pain, between the eyes. There is a profuse discharge of mucous into the nose and, as a rule, a great deal of sneezing. The latter symptom is more or less characteristic of impaired ventilation of the ethmoid and is perhaps the most characteristic symptom of the chronic hypertrophic form of ethmoiditis.

An occasional sequel of acute catarrhal ethmoiditis is the occurrence of a closure of an ethmoid cell, with retention of secretion, over a considerable period. It is associated with a sensation of fulness or pressure in the region of the ethmoid. Very often the condition is relieved, after it has existed for a few weeks, by the spontaneous discharge of a quantity of a lemon-yellow or straw-colored fluid from the nose. More rarely the condition persists as a chronic mucocele, with a gradual distention of the ethmoid cells, sometimes toward the nasal chamber, at other times toward the orbit, through the orbital plate of the ethmoid.

An acute purulent involvement of the ethmoid labyrinth, acute empyema, is not so common. In these cases the profuse discharge of pus into the nose may be associated with a great deal of pain, caused primarily by impaired drainage from the ethmoid cells. The result of the impaired drainage is the same in the acute empyema of the ethmoid as when this condition develops in acute empyema of the mastoid; the bony framework becomes involved. With the softening of the bony walls of the ethmoid there is likely to develop an extension into the orbit and, finally, an external fistula, which is usually located either just above or just below the inner canthus of the eye. When the ethmoid bone becomes involved in cases of acute empyema of the ethmoid the process is certain to persist as a chronic empyema unless the diseased bone is thoroughly removed by operation.

Of the chronic pathologic conditions involving the ethmoid, the most common and often the most troublesome form is chronic hypertrophic ethmoiditis. This is primarily a non-suppurative disease, but with the impaired drainage of the ethmoid cells, which the hypertrophy of the mucous membrane produces, the condition may become the seat of a secondary suppuration which persists after an acute infection as a chronic empyema.

The first change that takes place in the hypertrophic form of ethmoiditis is in the mucous membrane, which undergoes a polypoid degeneration. This involves the mucous membrane lining the ethmoid cells, as well as the covering of the nasal wall of the ethmoid, especially the unciform process and the bulla ethmoidalis. Later, the ethmoid bone itself becomes involved. The changes in the bone are the result in part of reabsorption of the bone, and in part of newly formed bone, the former, as a rule, predominating. The symptoms by which the hypertrophic ethmoiditis can be recognized are quite characteristic. The patient complains of symptoms of almost continuous acute head cold, attacks of sneezing associated with profuse water discharge from the nose, sensation of fulness and pressure between the eyes, etc. A careful examination of the middle meatus is often necessary before one can detect the characteristic polypoid degeneration over the exposed surface of the ethmoid. It is not always possible to determine the extent of the process involving the ethmoid by the changes observed in the middle meatus. Very often one detects only a few small polypi under the middle turbinate, when an opening of the labyrinth discloses an extensive polypoid degeneration of the membrane lining the ethmoid cells. The hypertrophic form of ethmoiditis is not infrequently a part of a diffuse hypertrophic process involving the lower turbinate bones as well.

The chronic empyema of the ethmoid cells occurs usually as described above: first, by the persistence of an acute empyema, because of the involvement of the bony framework when the drainage has been seriously impaired; second, by an acute infection taking place in the presence of a hypertrophic ethmoiditis—here the impairment of drainage keeps up the process as a chronic empyema.

---

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

There is a chronic atrophic form of ethmoiditis seen, as a rule, in connection with a general atrophic process throughout the nose. In these cases, the atrophy apparently begins in the mucous membrane of the ethmoid, but, just as in the remainder of the nose, this atrophy is associated with atrophy and shrinking of the bony framework. This atrophic process is, as a rule, bilateral, but it is not uncommon to find the disease limited chiefly to one side of the nose. We see it developing on the side where a deflected septum has produced a roomy nasal passage, as well as on the more obstructed side. It is in these unilateral cases especially that we should suspect some circumscribed process, such as a focus of pus in the ethmoid labyrinth, as the cause of the atrophy. This conclusion is borne out by certain cases in which circumscribed suppuration of the ethmoid is associated with an area of atrophy restricted to the immediate region of the ethmoiditis. I have seen a circumscribed area of atrophy in the recessus spheno-ethmoidalis in which chronic empyema of the sphenoid was found unassociated with any involvement of the other nasal accessory sinuses.

The cystic enlargement of the middle turbinated body and of the bulla ethmoidalis are often described as pathologic conditions. While it is true that these structures may be the seat of a mucocele which is causing them to enlarge, the enlargement is usually in the nature of an anatomic variation. These variations are quite common in the formation of the ethmoid labyrinth. It is not unusual, for example, to find a large ethmoid cell developing in the floor of the frontal sinus, or for an unusually large cell to develop at the expense of the other ethmoid cells. The aberrant ethmoid cells which occasionally develop in the middle turbinated body may become the seat of a chronic inflammatory process, just as may any other ethmoid cells. In most of the cases of cystic enlargement of the middle turbinated body the cell is free from any secretion.

Tertiary syphilis not infrequently involves the ethmoid, with extensive bony necrosis. In these cases the orbit is usually sooner or later involved and an external fistula forms in the region of the inner canthus.

The development of a primary malignant growth in the ethmoid labyrinth is occasionally observed. The first symptoms in these cases are likely to be those produced by a secondary involvement of the orbit, while in the nose there may be relatively little to indicate the serious character of the disease.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. HOLMES AND SHAMBAUGH

DR. ROSS HALL SKILLERN, Philadelphia: In 1909 when Uffernorde first brought out his work on the ethmoid he laid particular stress on the idiopathic, hyperplastic form. That is the form, of course, of polypoid degeneration and polyp formation. Previous to that time we considered that all polyps springing from the ethmoid region were due to some form of sinusitis, generally purulent, and when Uffernorde made that statement it was received with opposition by his German colleagues. It was taken up here, however, and now has come into general acceptance in Germany as well.

Uffernorde's classification really failed to bring out anything new. Twenty-five years ago Bosworth brought out a classification in which he mentioned this hyperplastic form. He divided ethmoiditis into six forms, and while some of these varieties were but different degrees of the same condition, nevertheless he anticipated Uffernorde in mentioning this distinctive form and so the priority belongs to an American. For operative purposes we can divide the condition of the ethmoiditis into the hyperplastic, the suppurative and a combination of these two. The hyperplastic may be extracapsular, the polyps being outside of the capsule without the cells being affected. The suppurative form may include one or more cells. As a rule, the suppurative ethmoiditis is limited to the anterior or posterior cells. Except in the atrophic form, suppurative ethmoiditis of the whole capsule is not frequently met. We may have a combination of these two forms, of course. The question has been raised whether the polyps cause the sinusitis or the sinusitis the polyps. It has been shown that when these conditions are in combination they are dependent on one another. There is an idiopathic form, in which pus never occurs, and again cases occur of the worst kind of purulent sinusitis in which polyps have never been seen.

This new operation has its place in certain conditions, the principal of which is when the middle turbinate lies close to the lateral wall of the nose, when it is going to be hard to infract the turbinate and get underneath it. Dr. Mosher short-circuits the whole thing. He makes a hole in a definite place where certain things are to be found underneath. At present the way we operate on the ethmoidal labyrinth is first of all to attack the uncinate process which stands out in front of the ethmoid capsule, sometimes from 0.5 to 1.5 mm. We break that down with the hook; that gives us this extra distance. The bulla is directly in front and we can easily resect it. In the past in operating on the ethmoid we failed to have a sufficiently clear idea of just what we proposed to do when we started out. We should be in the same state of mind as the general surgeon when he starts an exploratory operation in the abdomen, for example. He opens the abdomen but doesn't know exactly what he is going to do. We say, "Well, we will go in and take out the polyps and make a nice clean passage," but we know they are going to return sooner or later. Now if we make up our minds when we begin that we are going to take out these polyps and see what is underneath, and if necessary continue further back, we will be doing a more satisfactory operation. If we have definitely in view that we are going as far as the indications warrant, we will do better work and get better results.

DR. OTTO T. FREER, Chicago: Deep hyperplastic ethmoiditis, as I have found it, is more inclined to involve the anterior ethmoidal cells than the posterior, but may include the entire ethmoid labyrinth. In marked cases the middle turbinated body and all of the cell-walls except a few remaining spiculae of bone are absorbed and the lateral mass of the ethmoid bone is replaced by polypi tightly packed in a space bounded outwardly by the orbital plate, above by the cranial plate over the ethmoid cells and internally by the nasal septum. In such extensive cases, not rare, Dr. Mosher's landmarks are lost, but nature furnishes a guide in the form of the polypi and softened bone, the operator knowing when he has reached the boundaries of the disease because his curet encounters firm, hard bone. I employ Grünwald's sharp spoons, the Grünwald punch with its wide mouth, and also ring curets, as the ring form cuts best. It is necessary to curet not only to the orbital plate but also forward and upward toward the frontal sinus, as the frontal cells (Killian) are nearly always involved, blocking the outlet of the frontal sinus, so that, after their removal, the operator nearly always finds himself in the frontal sinus and close under the cranial plate. After the operation a large cavity is seen above the lower turbinate with hard walls and free from polypi. A consideration of the anatomy of the region, as given by Dr. Mosher, will show how great the need of caution is in deep operations on the ethmoid bone. The dangers of the operation are penetration of the orbital plate, penetration of the cranial plate over the ethmoid cells and entering the antrum of Highmore. The latter accident is usually without consequence, though acute maxillary sinusitis may occur. In two cases related to me by colleagues, penetration of the orbit was followed by blindness, the cause, in one case, being hemorrhage into the orbit; in the other, orbital abscess. To avoid such accidents the curets must be sharp so that they may be used without force and nothing must be done without the aid of sight. Working cautiously with curet and punch, and taking his time, the operator need not fear disaster.

Dr. George F. Cott, Buffalo: Dr. Mosher's operation is one of the neatest, cleanest, best operations for draining the ethmoid cells that has ever been proposed. In latent sinusitis many pathologic conditions occur, producing great discomfort to the patient, as rhinorrhea, excessive sneezing, etc., with apparently no affection of the sinuses. That is in the latent stage, in which there is no pus, perhaps no mucopurulent discharge, but if the cells are opened and cleaned out often almost immediate relief is obtained.

Dr. W. W. Carter, New York: I do not think we should ever operate in acute ethmoid inflammation unless there is distinct evidence of pus under pressure. With regard to chronic purulent discharge, we all know from the structure of the cells, the position of their ostia, that it is impossible for them to drain thoroughly unless an opening is made into them. The real indication for operation on the ethmoid should depend on the condition of the bony walls of these cells. It has been shown that one of the earliest changes in polypoid degeneration occurs in the vascular layer of the periosteum, that it is a passive hyperemia, producing an edema. The condition, therefore, of the bone is a pathologic one, and if the bone is diseased you must remove it. Therefore polypoid degeneration is a definite indication for exenteration. Since the introduction of the Mosher operation I have used it a number of times and have had excellent results. It has given me a confidence in operating in this region that I never had before.

Dr. F. W. Sears, Syracuse, N. Y.: I speak from the patient's point of view. I suffered for years from ethmoiditis, which had finally resulted in severe attacks of asthma. A number of operations were performed with practically no benefit. Finally a Baltimore specialist attempted to relieve the trouble by an operation under a local anesthetic, which did not relieve the ethmoiditis. The asthmatic conditions came on worse than ever during the following October. At that time Dr. Mosher, after having several roentgenograms taken, operated under a general anesthetic. I believe the anxiety and suffering from local anesthesia more than offsets the discomforts and dangers from a general anesthetic. The operation resulted in a complete relief from the asthmatic conditions and a rapid restoration to health.

Dr. A. L. Burdick, Lansing, Mich.: I was impressed by Dr. Shambaugh's remark in which he compared the ethmoid to the mastoid labyrinth. I do not know why this is not oftener done. I was called to see a patient who had fever and intense pain, and exophthalmos of the left eye. There was a history of chronic nasal discharge for fifteen years. On examination the condition was undoubtedly one of purulent ethmoiditis. Four hours later I operated and removed literally sacs of pus, the sacs made up of the lining of the ethmoid cells. After three hours the pain was gone and the patient was practically well. In this case there was abscess of the orbit, but it was not followed by blindness.

Dr. G. W. MacKenzie, Philadelphia: We may classify the condition into different types, but there are all grades of these different types and every case becomes individual. Conservative treatment is important for that reason. A patient came to me who had been operated on on the right side of the nose for frontal sinusitis, accompanied by maxillary sphenoiditis and more or less ethmoidal disease. It was on the concave side where there was a considerable deflection of the septum. I washed out each of these cavities and could find no involvement of the cells at this time. The patient, however, had an accumulation of mucopurulent secretion over the posterior part of the septum and more or less on the lateral wall. I cleansed it thoroughly and inspected the parts with the Holmes endoscope, which is advantageous in examining that region. After having assured myself by these methods that nothing was present, I sent the patient to two roentgenologists who made various roentgenograms, none of which showed positive indications of sinusitis. I then tried the experiment of plugging the right side of the nose with cotton sufficiently to filter the air breathed in this wide-open side. The patient reported the next day saying that he had no secretion. I tried the experiment several times and have since tried it in other cases, and I find that when there is sinus disease, on removing the cotton there is a jelly-like secretion and when no sinus disease exists there is practically no secretion. This led me in this case to do a septal operation with most favorable results.

Dr. Charles R. C. Borden, Boston: I emphasize an important point made by Dr. Holmes. The second turbinate is a valuable structure and should be preserved as much as possible. In the early cases it is possible to save a considerable portion of it. Removing the anterior ends of the turbinate is poor surgery if it can be avoided. In cases in which simple drainage is desired I perform a modification of the Mosher operation, using a biting forceps in place of a curet. I have had several unfortunate complications following the use of a curet and consider it a dangerous instrument. It is a comparatively safe and simple procedure to open the anterior ethmoid cells at Mosher's point of election with a biting forceps, making a long narrow pathway through the body of the ethmoid until normal bone is reached. A little force is required to make the first bite, but after the cells are reached they cut away with surprising ease. One is often amazed at the large number of small polypi which will come away in the mouth of the forceps when none were suspected of being present. The curet usually fails in this respect, as that instrument simply pushes the polypi aside. Of course, in advanced cases, this method of procedure will not be sufficient. In the early cases, however, it not only provides the desired drainage, but removes the polypoid tissue and at the same time leaves a considerable amount of healthy tissue in place, which is desirable for the welfare and comfort of the patient. In the advanced cases I perform the Mosher operation, using both biting forceps and the curet as it is practically impossible to use the forceps alone. I have known several cases of meningitis to follow operations and great care is needed in doing them with any form of an instrument.

Dr. John O. Roe, Rochester, N. Y.: After listening to Drs. Holmes, Shambaugh and Mosher, one would naturally get the impression that operations on the ethmoid sinuses are simple procedures and that to enter the ethmoid sinuses and curet or cut away diseased tissues is comparatively free from danger. I therefore call attention to some of the dangers connected with these operations, especially in the hands of amateurs. Recently two deaths occurred in Rochester following nasal operations. These deaths, however, are not the only ones to be referred to, for the report of cerebral complications in nasal surgery are too frequent to be reassuring to the amateur, and it is only by those experienced in this line of work that such operations should be undertaken. I agree with Dr. Borden as to the advantage of biting forceps over the curet in many cases. When the walls of the ethmoid cells are quite thin and more or less fragile, the curet has its advantages, but in cases of more rigid walls, I have found the biting forceps much superior. For the anterior ethmoid cells I use the straight biting forceps, similar to those mentioned by Dr. Borden, but for entering the posterior ethmoid cells, I use forceps that I have had made, with cutting blades set at right angles to the shaft of the forceps, which I have previously described. In many of these cases we find marked enlargement of the turbinal cells of the middle turbinate body, completely blocking the central portion of the nasal fossae. In dealing with these cells, I first determine their presence and extent by puncturing them at their anterior portion with a slender bistoury. In a large majority of cases, the knife will enter the cells freely, indicating at once the nature of the conditions we have to deal with. With the straight forceps the outer wall of these cells is taken away, then by fracturing and forcing outward the inner wall, the nasal passage at this point is made free, while at the same time a mucous membrane forming a covering for this outer wall, is preserved. Before entering the posterior cells with the rectangular forceps, or even with the curet, it is of the utmost importance to locate carefully the posterior wall of the nasal passage, particularly in the region of the cribriform plate. This I do with a slender flat probe, made of steel, the distal end 4.5 mm. wide and very thin. It will go where the round probe will not, and with it the exact location and condition of the parts can readily be determined. This little instrument I have found so exceedingly serviceable in all such work, that I have dubbed it "my long finger."

Dr. H. Wilson, Detroit: If I do not err in my understanding of the essential nature of Dr. Mosher's operation, the use of biting forceps in exenterating the ethmoid labyrinth goes aside from the spirit of the operation itself. I recall no other nasal operation which is exactly the same as Dr. Mosher's. It depends for its success on the ability of the operator to visualize the anatomic and pathologic conditions that exist at the end of his curet. Without this, one cannot properly execute the operation. The ability that we possess to translate the impression we receive from biting forceps fails to meet the requirements of the operation. It seems to me, however, that that is the crux of the operation itself; that is what makes it different from all other ethmoidal operations. It begins at a different point and we know our landmarks from that point on. As to the serious results spoken of, no one has a right to perform such an operation who has not acquired this power of visualizing the anatomic structures he is engaged in operating on. Failure to be able to do this may be the cause of the unfortunate results that Dr. Roe and others have referred to.

Dr. Joseph C. Beck, Chicago: It is important to amplify the gross pathology of ethmoiditis. The names of three men should be mentioned in referring to the pathology of ethmoiditis—Woakes, Uffernorde and Wright. Last year I presented at the meeting of the Laryngological, Otological and Rhinological Society the subject of the histology of ethmoiditis, in which I showed the varieties I had found in my own practice. The bone and periosteum show the greater change, except in the acute cases. There is a distinct difference between polypoid and inflammatory edema of the mucous membrane and it will make a great difference in the results of operation. In the hyperplastic form, imperfection of the bone and periosteum are essential points in the pathology, not secondary changes from infection; it is a degenerative process. It would be well for men to study their clinical cases and make a few sections showing where the disease is in individual cases. Two years ago this operation was demonstrated to me by Dr. Mosher. I went home and tried it on one side, the old method on the other. Now I use no method but his. If some one comes and tells us of blindness occurring in a certain case, thus putting a damper on such an operation, we should know who such operators are. It should not frighten expert men away from doing a good operation.

Dr. Lee M. Hurd, New York: Sometimes instead of the papery shell-like bone of the ethmoid we find it very thick, from 1 to 1.5 mm. of hard bone. In one case I could not get through. We find necrosis of the bone of the ethmoid cells of a non-specific nature at times and we do not get the condition well unless we exenterate the entire labyrinth. Taking out the polyps alone is like cutting the heads off dandelions. To get a cure we must do an exenteration. How does Dr. Mosher get at the prolongations of cells over the orbit? A straight curet will not reach these. I have been injecting Beck's paste into any remaining cells that cannot be reached at the operation and it seems to aid.

Dr. E. M. Holmes, Boston: I do not want to give the impression that I am opposed to operative procedures in the treatment of ethmoiditis. I thoroughly appreciate the work of Drs. Mosher and Skillern and others and am glad to see this operative improvement, but my paper was as I said, conservative, because we are seeing so much operative work, extensive exenteration, by men who are new at the work and who have not had sufficient experience. It is much easier for them to sacrifice all the structures in the nose than properly to study the case. All tissue which can be should be saved so that all the functions possible may be conserved. We all find cases in which polypoid degeneration extends to the upper and outer wall of the ethmoid cavity, even after thorough operation. It may be our duty even to remove a portion of the orbital plate.

Dr. George E. Shambaugh, Chicago: Perhaps the most interesting pathologic condition involving the ethmoid labyrinth is the condition first described by Woakes, which we now recognize as the non-suppurative hyperplastic ethmoiditis. It is often the most difficult to recognize and is the cause of the most troublesome and, in a way, the most interesting symptom. It is this form which is often associated with asthma. The early symptoms are those of recurring acute head colds, sneezing attacks, etc. I received a shock some years ago when Dr. Bosworth described his method of curing recurring acute head colds. He stood behind the patient and with an electric burr reamed out the ethmoid labyrinth. We now recognize that he was operating for the relief of symptoms caused by hypertrophic ethmoiditis. We are doing the same thing now, only not quite in the same way. The one thing most essential in operation on the ethmoid is that the operator have a clear conception of the anatomy of this region. Unless he understands this thoroughly he has no business operating. To my mind not the least important part of Dr. Mosher's work has been to get our men interested in acquiring a better knowledge of the anatomy of this region. I am accustomed, when operating on the ethmoid, to do the work under local anesthesia. I usually remove a part or the whole of the middle turbinated body; then with a Hartman nasal forceps I begin in front and break through one cell after another until the whole labyrinth has been exenterated. The work with the forceps requires but a few seconds to complete. If one direct the pressure outward, backward and upward, one keeps clear of the cribriform plate. For this reason I like to leave standing the mesial wall of the labyrinth. The roof of the ethmoid labyrinth is a firm bone, whereas the cribriform plate is very fragile.

Dr. Harris P. Mosher, Boston: We have many good methods of getting into the ethmoid, but we want, more than anything else, a better idea of the pathology of ethmoiditis. I have found that non-success in getting into the labyrinth easily in this way is often because the curet is not placed high enough up or far enough back. Dr. Skillern says go as far as the pathology in the particular case warrants. That is the right idea. Dr. Freer said that in many cases of degenerative process there are no landmarks; that they have been destroyed. Of course that is true, but if one has a systematic procedure to follow one will not be in danger. As to the use of biting forceps rather than the curet, I prefer the curet until I find out where I am, and then I use the biting forceps. I use it freely after I have secured orientation with the curet. As to the serious results spoken of, anyone who does work on the ethmoidal labyrinth without a proper anatomic and surgical preparation simply has no surgical conscience. I agree with Dr. Wilson that to be able to visualize the operation is the main thing. As to Dr. Hurd's question about the cells that extend out over the orbit, they are, as he says, difficult to reach; I simply do with them the best I can. Dr. Shambaugh says he leaves the middle turbinate. I use the middle turbinate as a landmark to keep me in the labyrinth and to keep me away from the olfactory fissure. Then when I have cleaned out the labyrinth I remove the middle turbinate to free the front face of the sphenoid.

I. THE SECTION ON STOMATOLOGY: ITS NEEDS, ITS DUTIES AND ITS OPPORTUNITIES. II. THE FIELD OF STOMATOLOGY*

WILLIAM C. FISHER, D.D.S.
NEW YORK

I. ITS NEEDS

I do not think there has ever been at any time in the life of this Section any question as to the quality of the membership or of the caliber of their intellect, but I do know that the numerical strength of our membership and more particularly the attendance on our scientific meetings has more than once been a subject of regret and even concern. Time and time again have excellent programs been prepared and presented to an audience so small as almost to discourage the essayist and embarrass the members. Therefore, I venture to state that one of the great needs of our Section is increased attendance and that can be the better accomplished through increased membership. Understand I do not for one moment think we should lower the high standard that has been so diligently maintained by those who have in the past years guided the affairs of this Section. And it is not necessary to lower our standard one particle. There *must be* hundreds of able men of the dental profession who if an invitation was extended to them would be pleased to affiliate with this Section of the Association and in so doing bring profit both to themselves and their Section.

The great amount of scientific information developed and presented in this Section every year is of great value to the general practitioner of dentistry, as well as the specialist in the several branches of oral surgery; therefore I contend that this Section on Stomatology is not performing its duties until it makes possible such a dissemination of scientific medical dental knowledge. According to the Constitution of the American Medical Association the degree of M.D. is not necessary for associate membership in several of its Sections, and of this number, the Section on Stomatology is one. And in its particular case the associate member need only possess the D.D.S. degree. Now this is not generally known. The idea most commonly entertained throughout the dental profession is that the additional degree of M.D. is necessary to qualify for membership in the Section on Stomatology. And also I have heard it stated time and again that the average dental practitioner could not grasp the papers presented here. This may or may not be true, but if true does it not just as aptly apply to any and all of the sections of the A.M.A. and their respective membership?

We must be a little more liberal and admit to our Section good men of the dental profession. Yes, even urge them to join us, if we wish others to receive the benefit of these excellent programs.

PART II. THE FIELD OF STOMATOLOGY

What is it? In other words where does the practice of dentistry, or stomatology, if you wish, end, and where does the practice of medicine begin? To what point may one possessing only the D.D.S. degree go in the treatment of oral infections; and if my question will not appear too foolish, to what point may a person possessing the M.D. degree go while in the same field. Some of you at this moment are wondering why I raise such a question and what can be gained by it. I raise the question for this reason: that there are at present many men possessing both the M.D. and D.D.S. degrees but licensed by their state to practice only dentistry. They are, I feel sure, frequently in their daily routine trespassing on the territory of the medical practitioner.

Now, legally, these gentlemen are no better off than the man possessing only his D.D.S. degree and so licensed. But I am sure many of the former class have not quite realized this and in their enthusiasm to care for their patients have lost sight of the fact that there must be some point at which the practice of dentistry stops and the practice of medicine begins.

Where that most aggravating point may be, your chairman is not going to dare even to suggest. But it does exist. And the presence in the dental profession of men with great scientific and medical knowledge, which they are daily applying more and more to the practice of dentistry, becomes almost a serious question as to just how far this dental practitioner may go and yet obtain the protection of the law for his acts. Sooner or later the several state legislatures will find it necessary to locate and define this dividing line and it is for this reason that I at this time raise this question, that you may give it serious thought. So that, when the time comes neither the dental nor the medical practitioner shall be hindered in his work, or what is more important the public shall not be deprived of the skill of even one man.

Do not understand me to say that scientifically there is any dividing line between the practices of the two professions. It cannot possibly be located, for it does not exist, but legally it does and we must define it or better define and remove it.

373 Fifth Avenue.

ABSTRACT OF DISCUSSION

Dr. John S. Marshall, Berkeley, Cal.: I have always been intensely interested in this section, and when Dr. Talbot and myself and some of the older men joined it we had to have the medical degree; no one was eligible else. The object in organizing the section was, as Dr. Fisher has indicated, to disseminate dental knowledge to the general medical practitioner. That has been the object all through the history of this section. I believe this section has been the leader in many things with regard to dental medicine and dental surgery. Of course, at first, we realized that, inasmuch as the medical degree was a prerequisite for membership, we could never be a large body. Some may remember that when the Association met in Chicago in 1886, Dr. Allport introduced a motion making dental surgeons with the D.D.S. degree eligible to membership, provided they came from colleges which had the same preliminary requirements that the medical schools had, and that did the same work in the fundamentals, chemistry, physiology, anatomy, etc. That was passed unanimously. Later, after I went into the United States Army, some change was made in the constitution whereby we have regular members who have the D.D.S. degree and also associate members. That has not added materially to the size of our section. There seems to be something lacking to build up the section; what that is I am not prepared to say. I want to make this suggestion, however, that we take up original investigation and present it to the Association as presented to-day by Dr. Price as part of the work done by the Research Commission of the National Dental Association. Our work has always been in the preparation of papers on those subjects that we consider vital for the medical man to know, and these have been read with a great deal of avidity, and altogether we have done much toward bringing before the medical profession the real benefit of a thorough knowledge of dental diseases and their application to general medicine. I should be glad if this old idea of separation between medicine and dentistry could be obliterated. There is a coterie of men always talking about the dental profession as separate and distinct from medicine. I have always talked about dentistry as a department, a specialty of medicine, as much so as that of the eye, ear, nose or throat, or obstetrics and gynecology; but there is a feeling, and statements have been made by older men than myself in the profession, that they did not want to be the tail to the dog. I think it is a good thing to be the tail sometimes, provided you can wag the dog. I believe the time is coming when the distinction between dentistry and medicine will be wiped out and we will be simply called dental specialists instead of a separate profession of dentistry.

---

* Chairman's address read before the Section on Stomatology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, June, 1914.

Dr. H. L. Wheeler, New York: I am desirous of getting some information. I find written across my membership card always, and I have been a member of this section for many years, "Associate Fellow." Can anyone tell me what that means?

Dr. E. S. Talbot, Chicago: I cannot answer that.

Dr. F. B. Moorehead, Chicago: If you became a member through your state medical society, you should be a Fellow.

Dr. Wheeler: I am a D.D.S.

Dr. Moorehead: Then you are simply an "Associate Fellow."

Dr. Wheeler: That is the rub. I have no inclination to apologize for being a D.D.S. I have the medical certificate from the regents of the state of New York, but a great many dentists feel that there is a distinct line drawn between the degrees of M.D. and D.D.S., to the disadvantage of the D.D.S., in an organization composed largely of men with the M.D. degree. I feel it because I have probably done more organizing of dental service in hospitals than any other man in the country, and I have had that same difficulty in New York, which has dealt absolutely fairly with the dentist from start to finish, and there, at present, dentists are on the same footing as medical men, getting the same titles and the same pay in every department in which they serve. I believe this section has been useful and I believe that it can be made more useful. I believe, as Dr. Marshall has said, that our profession is a specialty of medicine. I have no sympathy with the idea of dentistry's being a separate profession any more than I feel that it is necessary for me to apologize for being a D.D.S. and nothing else. I believe that the D.D.S. covers that specialty thoroughly and completely, and that if dentists are wanted to attend these meetings they must be given to understand that there is no discrimination between men; that if one has the ability it does not matter what degree he holds. When the profession is convinced that whether the M.D. degree is or is not held, if a man holds the D.D.S. degree and shows ability to work substantially for the good of the healing art, I think we will have a much larger membership than we now have. I do not mean to infer that the attitude of the section is against the man who holds only the D.D.S. degree, but there is a great misunderstanding with regard to it which needs to be rectified. For instance, members of this section in New York have attempted to establish special service in the hospital in New York, and have insisted that if dentists were to have the recognized position they must have the M.D. degree. You cannot successfully establish such service if that policy is followed out. I have told them, and it is a fact, that in no institution in which the M.D. degree was insisted on have they got any further than the extraction of teeth. The institutions in which they have taken care of the mouth and teeth, in which they are working with the physicians, visiting the wards, and looking after the mouths while the physician is looking after the rest of the body, are the institutions that have taken the dentist without regard to degrees. I am grieved that there should be any difference of degrees when it comes to dentistry, and I believe the quicker that can be ignored the more quickly will institutions of this kind increase their strength.

Dr. E. S. Talbot, Chicago: I shall have to correct both Dr. Marshall and Dr. Wheeler with regard to the matter. There is no difference in their standing, except in degree. As Dr. Marshall has said, when the resolution referred to was passed, dentists were put on an equal footing and we have never had a single instance in which there has been any discrimination from that time. I have repeatedly explained this condition to various men and if dentists do not understand it, it is their fault. There has not been a single instance come up in the section in the House of Delegates or in the general body where the dentist has been discriminated against in any way.

Dr. Marshall: Is that so to-day?

Dr. Talbot: Certainly it is so to-day. Every dentist in this section has the same privileges as the medical men.

Dr. M. I. Schamberg, New York: After listening to Dr. Talbot's explanation that there is no discrimination between dental and medical members of the Association, I call attention to the fact that my card likewise records me as an associate member, and at times it has been worded "dental member" although I hold both the medical and dental degrees. When I came into the section I was a member of the Philadelphia County Medical Society, and I was not even aware that my name came from any other source than through the county medical society, so that I have been surprised to be recorded as a dental member of the American Medical Association. That, however, is a trifle, because, as Dr. Talbot has said, there has been no discrimination at any time by the medical members toward the dental members of this Association. Several points mentioned by Dr. Fisher are of vital importance not alone to the members of this section but to many men practicing throughout the country whose status is not definitely defined by the law, or is not definitely understood. At present I am practicing in the state of New York under a dental license, having been unwilling to submit myself to the humiliation of passing the medical examining board ten or fifteen years after I had finished with the elementary subjects. This, however, every physician has to contend with when moving from one state to another, and makes it imperative that the legislatures of the various states should consider that dentists are primarily medically educated; that we take the elementary medical subjects whether or not we hold the medical degree, and that it is merely coincidental that dentistry has developed as it has in the separate schools. Many men with the D.D.S. degree are as able to perform operations in and about the mouth as we who were fortunate enough to have extended our work a year or so and acquired the M.D. degree. Dentistry is in truth a specialty of medicine and there should be no distinction between the two professions. I believe that, in time, the specialties of ophthalmology, otology, gynecology, etc., will be acquired as dentistry is. This is distinctly a day of specialties, and I believe that men in other specialties are less fitted for special practice on the day of graduation than are the members of the dental profession. It requires special instruction, and dentists have been receiving this and also instruction in the fundamental principles of medicine. Dr. Fisher's address should not be casually passed over. I believe dentistry should be defined in the statutes of the various states.

Dr. G. V. I. Brown, Milwaukee, Wis.: I have given the better part of the last few months to consideration of this subject. It is a pretty good time now for us to clear the atmosphere of these doubts so far as may be possible, and when we get into it a little more deeply there are some very distinct underlying educational questions which must in some way be satisfactorily answered before we can entirely dispose of the matter. I have been trying to suggest a way by which we may ultimately find out where we stand.

With regard to Dr. Wheeler's question, here is the difficulty with regard to membership; when the dental colleges agreed on a four-years' course, the dental members were on a par with the medical men and no difference was made, but when they went back to the three-years' course, there must necessarily be some distinguishing mark between the man who has three years and the man who has four.

Dr. Wheeler: The dental colleges are coming back to the four years' course.

Dr. Brown: I think they are coming to that, but until then there must be some distinction. It does not make any difference either in the conduct of the sections of the Association or their members, but nominally there must be a difference.

Dr. R. H. Ivy, Philadelphia: There is a way in which the section might bring the dental profession closer to the medical profession. The papers of different medical journals are abstracted each week in The Journal of the American Medical Association, and it might be possible through this section to have some of the papers appearing in the dental journals abstracted, as many of these papers are of interest to the medical profession. In that way much of the work of the dental men with regard to oral sepsis and other things would be directly brought to the notice of the medical profession.

Dr. William C. Fisher, New York: I did not purposely bring out the difference in the standing of the members. My idea was to bring to your attention facts which I thought possibly many had forgotten. Dr. Marshall seemed to think that the object of this section was to educate the members of the medical profession in things dental. I think if that was the object of it in its organization, we certainly should widen the scope and also educate dental men in things medical.

THE SECTION ON STOMATOLOGY AS A FACTOR IN THE EVOLUTION OF DENTAL AND MEDICAL SCIENCE*

GEORGE V. I. BROWN, M.D.
Oral Surgeon, Children's Free Hospital and St. Mary's Hospital
MILWAUKEE, WIS.

Recent advancement toward more general recognition of the pathologic influence of oral affections as factors in disease has been so great that almost every thought of distinction between those who treat disorders of the teeth, and the practitioners whose ministrations are directed to the relief of such distress in other anatomic regions, or of the organism as a whole, has been swept as driftwood before a tidal wave in the common desire of a great humanitarian impulse that brooks no trammel of limitation by degrees or titles.

Surely this is an age when dreams come true, for the visions that inspired the speech and directed the pens of such men as Alkinson of New York, Garretson, Bonnwill and Flagg of Philadelphia, Allport of Chicago and their contemporaries in early years touching as they then did the very boundary limits of the heights of empiricism, are now becoming prophetic in the light of actual scientific demonstrations of their truth.

In like manner the foundation laid with the help and guidance of the master surgeon, Samuel D. Gross, and the great builder of medical associations, Dr. N. S. Davis, and the little band of dentists who joined hands as organizers of the Section on Dentistry, now the Section on Stomatology of this great body, the American Medical Association, has become the underlying support of a rapidly extending scientific edifice. It is obvious that this superstructure can be sustained only by an ever-increasing broadness at its base; otherwise this influence must perish. It therefore seems advisable at this time to glance backward along the recorded pages of the thirty-two years of the Section's existence, and then to scan as best we may the already forming, though ill-defined, outlines of the possible future requirements in this division of medical science.

At a meeting of the American Medical Association held at Richmond, Va., May 3, 4, 5, and 6, 1881, there gathered together for the purpose of forming a Section on Dental and Oral Surgery the following organizers: Drs. W. W. Allport, Chicago; Huxhurst, Grand Rapids, Mich.; Eugene S. Talbot, Chicago; T. W. Brophy, Chicago; J. A. Williams, Boston; George L. Parmlee, Hartford, Conn., and D. H. Goodwille, New York. At that meeting Dr. Samuel D. Gross of Philadelphia asked for a suspension of the regular order of business and moved that the By-Laws of the Association be so amended as to create another Section to be known as No. 7 and entitled Dentistry. This was made effective the following year.

The first meeting was held at St. Paul, June 6, 1882. It is especially interesting in view of later events to note that at this time Dr. Allport offered a resolution providing for the appointment of dentists in the Army and Navy and to cooperate with Dr. Maynard of Washington for this purpose.

The resolutions of sympathy spread on the records of the Section, as they from time to time mark the passing of some important member, bear the stamp of a depth of feeling that cannot be measured by ordinary standards because each one of these far-seeing men was an integral part of the little group that was laboring for higher things in the progress of dental science.

My purpose in presenting this brief reference to the past is not so much an endeavor to do justice to faithful individual effort during a period of thirty-two years, deserving of such praise as the work may be, as to try to present in just the right way, if possible, the whole scheme of the present status of the pathology and treatment of tooth and mouth affections in their common relation to other diseases and incidentally to assist in clearing up the confusing conditions which pertain to the professional association of those who treat them, whether distinguished by the degree of D.D.S. or M.D. or both.

I fully realize that it will be next to impossible for me to state in exact terms just what this relationship, or state of interdependence, should be, for no one really knows and no two of those who ought to be best informed have ever been able to state their views similarly. Yet for this very reason there is even greater need of proper treatment of this subject.

To picture comprehensively the real influence of the work of this Section, one should have in mind, first, the all-important part that the mouth plays in the etiology of disease, as a source of focal infection, a cause of local or general nerve disturbances, and a factor in developmental, digestive, circulatory and other disorders; second, a just idea of the constructive benefit of the steadily continuous presentation of these subjects during thirty-two years in a section of the largest and best-recognized medical organization in this country, and of calling the attention of medical practitioners to this particular field in a specific way through the medium of their own medical journal; third, it should be understood that in the past too much attention has been given to degrees and much harm done through failure of dentists generally to realize that strictly dental organizations bear precisely the same relation to the Section on Stomatology of the American Medical Association that the special societies of other divisions of practice bear to their respective associations.

---

* Read before the Section on Stomatology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

For example, the sections on surgery, internal medicine, eye, ear, nose, and throat have their corresponding associations in the American Surgical Association, American Neurological Association, American Laryngological, Rhinological and Otological Society, American Dermatological Association, American Association of Obstetricians and Gynocologists, etc., just as the dentists have the National Dental Association. There should be no question of loyalty involved in consideration of attendance on both.

When the members of the National Association of Dental College Faculties voted to extend the courses in their colleges to four years, the American Medical Association promptly accepted dentists to full membership in this body; but when the colleges decided to go back to three-year courses for graduation, it was obvious that there must be some distinction between men who have had four years' training when considering their association with those who have had only three. Thus dental graduates came to be accepted as associate members, but there is no appreciable difference between these two forms of membership in the conduct of section work and there ought to be a more general understanding of the fact that every dentist in this country has profited in some degree at least, professionally, socially and even personally, by the good work that this Section has accomplished.

There are grave questions to be met if dentistry is to hold her own in the advancement which marks the modern appreciation of pathologic and therapeutic considerations. This is no time to cavil about degrees. The true standard in rating the future practitioner in that branch of the healing art which directly relates to oral affections must be the measure of his knowledge of medical science, and his ability to cope with the requirements of a more or less radically changed order of practice.

From an educational point of view this means that the formerly so-called theoretical branches of the curriculum of his special college courses are after all in reality the very practical ones. Students of dentistry can no longer be permitted to skim through these studies and pass out into active practice with only a superficial knowledge of them. Anatomy, physiology, physics, chemistry, biology, histology and pathology are quite as necessary for them as for their brother students in general medicine. Obviously this cannot be accomplished under the plan of instruction as now given in preparation for the D.D.S. degree.

If, as Rosenow and other investigators have apparently proved, the principal sources of focal infection are found in the tonsils, the mouth, teeth, nose and nasal accessory sinuses, and if, as he also states, pathogenic micro-organisms can be harbored in these situations during the period of transmutation by which they may assume an increased virulence which makes them accountable for such diseases as ulcer of the stomach, rheumatism and its well-known chain of far-reaching symptoms, for endocarditis, myocarditis, gall-stones, and joint affections, and if in addition it can be shown, as we believe it can, that by proper care of the teeth and direction of the development of the dental arches, the pathologic conditions of both the tonsils and the nasal accessory sinuses can in large measure be controlled or prevented, then it must be accepted that full medical training is as essential for the one who has charge of the welfare of this fertile field for the propagation of disease, as it is for those who undertake to treat the general bodily manifestations thereof.

This does not of necessity mean that a student must first pursue the regular four years' course in medicine with the additional premedical and postgraduate years of studentship that are now being urged as necessary for proper training for the practice of medicine, and in addition a full course of two or three years more to complete his equipment for the practice of dentistry.

Desirable as these long years of preparation may be, and admitting to the fullest extent the value of the knowledge that might thus be acquired, there are nevertheless certain definite reasons why such preparation for the practice of dentistry is not practicable under present educational conditions.

Lest my position be misunderstood in view of this statement, and others that follow, it seems advisable for me to state that according to my belief it will no more be possible for dentistry to continue permanently as a profession distinctly apart from medicine than it was for the United States to exist half slave and half free, as recognized by Lincoln.

There must ever be some common meeting ground for all who practice legitimately every branch of the healing art. That has been, and will be with steadily growing recognition of its importance, the office of this, the representative stomatologic division of this great medical body.

Beyond a doubt there must come in the course of time the adoption and general use of degrees to distinguish the several medical divisions. Men without special training in surgery cannot be permitted to continue indefinitely to undertake grave surgical operations simply because they have qualified to the extent of a medical degree and a state board examination of general character. This is equally true of eye and ear, or nose and throat, or other limited practitioners, and they also should be required to have distinct evidence of preparation for their particular field of work.

With the continued extension of the required number of years of medical study and the very evident need of additional training for special practice, it would seem that in the course of the evolution of educational conditions there would ultimately be established a fundamental course of study which all must complete before taking up a special division of practice. The number of years required for this foundational preparation would be somewhat less instead of more than is now required for the M.D. degree, and the student after having completed this course could then in two years more of special study prepare himself for the degree which would represent his actual life work more completely than is usual at the present time. The following opinion expressed by Dr. E. C. Kirk is of interest because he is in charge of the Thomas W. Evans Museum and Dental Institute and therefore in control of the largest structure in the world exclusively devoted to dental instruction. As this institute is designed to give both undergraduate and postgraduate instruction, the views of one who is to direct its course are important in this relation.

> It seems to me to be inevitable that in the course of time a rearrangement of the medical curriculum must result from the specializing tendency, and from the increase of bulk in medical knowledge, both of which factors have made it

impossible to educate any man in medicine so that he can cover the whole ground.

That reorganization will, I think, take something of the following form: A sufficient length of time in the medical curriculum will be devoted to the training of men in all of the sciences that are fundamental to the entire field of the science and art of healing, and the termination of that phase of the curriculum will be marked by the conferring of a degree which will be educationally equivalent to the bachelor's degree in science and letters, and from the point of attainment of the bachelor's degree in medicine the student will specialize in groups of studies that will make him an efficient practitioner in some recognized special department of medicine at the termination of which he will have conferred on him his doctorate in medicine, and he will be licensed to practice only within the limits of the specialty for which he has been trained. Should he desire to acquire the right to practice an additional specialty it will be necessary for him to prepare himself by further educational work in another special department, and then secure the license to permit him to practice in that department, and so on.

It may be too much to demand such sweeping reforms in medical education until such time as in the course of natural evolutional progress these changes gradually may be inaugurated. There is, however, an immediate necessity for more thorough education of students who are to become dental practitioners in the branches of study in which their courses parallel those of their brothers in medicine. Without delay these fundamental medical sciences should be given exactly the same as for students of general medicine, and a passing mark on any one of them should be considered equivalent in every way, no matter what branch of practice may be contemplated or selected. Thus, the dental graduate will not only be more thoroughly prepared for his special division of practice, but he will also have so many definite credits toward the medical degree that he may reasonably be able to complete this course also without too much hardship. In due time it will follow that increasing numbers of the most promising students will complete their double education and take both degrees. Ultimately through the selective influence of a more enlightened laity the two degrees will be required.

Dealing practically with the educational difficulties that lie in the way of idealization in this educational formula, we find that in the absence of certain necessary but apparently impossible changes in the underlying primary courses of instruction, by the time the average student could complete his literary course with four years leading to a degree in arts, or science, and then four years in medicine, with the very necessary hospital internship of one year more, in a majority of cases he will have reached such an age that the first enthusiasm of his career will be lost. It is a grave question if the average result would be as good as it has been in the past when an aspirant for a medical degree was allowed to enter the medical college with but little if any more preparation than a high-school education. But leaving that much-discussed question for the settlement of educators now battling with it, there at least can be no question regarding the probability that at this advanced period of life it would as a general rule be quite impossible for an individual to acquire the necessary manual dexterity for successful dental practice. It would seem then that the best that can be done at the present time is so to arrange the curriculum of the dental student as to make it possible for him to have full training in the technic laboratories from the very beginning of his course, and to take during his first two years as many of the strictly medical studies as he can carry and complete in each the full regular medical student's course in these branches.

Obviously when the medical student's first and second years are crowded to the limit of average capacity, the dentist cannot do all this thoroughly and spend approximately forty hours a week in dental technic laboratories beside. Every teacher of anatomy or physiology or other similar branch can testify to the difficulties that have presented themselves when this has been attempted. By distributing the work and making the courses for the dental degree extend through four years instead of three, then with all this work out of the way, one year more could be made sufficient for acquirement of the medical degree.

Our problem is thus a problem no longer and the dentist is now a completely developed specialist in his work. Whatever the final solution of the complex professional relationship may be, it is at least apparent that the influence of this section, past, present and future, will be instrumental in its final adjustment.

The horizon from a dental and oral outlook appears wonderfully bright at the present time. The establishment of free dental clinics in many of the principal cities of the United States, examinations of the mouths of schoolchildren, lectures on oral hygiene under state appointment; endowed institutions for the care of the mouths and teeth of the poor and the systematic education and training of dental original research workers, supported by funds contributed for the purpose, are some of the many evidences that might be cited of the undisputed right of this stone rejected by the medical builders in 1840 to a place in the great temple of medical science.

Who can doubt that the cumulative effect of the long years of faithful educational service that the members of this Section have rendered has been a potent influence in the preparation of the soil in which the seeds of the various movements have given such gratifying evidence of fertility? Above and beyond all other factors, the usefulness of the work of this Section must be attributed to our secretary, Dr. Eugene S. Talbot, who has made it his life work, and who for years has directed the broadness of the scientific policy that has shaped the character of the program from year to year.

Next to this the most active influence has been the earnest cooperation and assistance of Dr. Simmons and his predecessor, Dr. Hamilton, as editors of THE JOURNAL of the American Medical Association, without which there could have been no such wide spreading of the truths of the gospel of oral medicine.

For the future the most desirable consideration appears to be a closer union between this Section and the state, county and national dental organizations such as may lead to increased cooperative activity. This would also lead to a more widely extended recognition of the value of this link in the chain of medical specialties which has been so carefully welded and forged and tried in the fire of these many years, in order that it might be relied on to hold with sufficient security its own representative division in proper relation to all other parts of the associated body of the sacred order of those whose mission is to mitigate and relieve the ills of suffering humanity, whose common purpose is to render human life happier if not longer and at least a little more worth the living.

445 Milwaukee Street.

ABSTRACT OF DISCUSSION

Dr. Joseph Head, Philadelphia: Dr. Brown's paper states clearly a fundamental thought that has been in the mind of every intelligent dentist since he began to practice. The dentist ought to be so perfect a mechanic that such perfection would be considered a goal easily sufficient for a life occupation; but the dentist also should be a thoroughly trained physician. We find that the mechanical appliances of dentistry which heretofore have been considered independent of a knowledge of medicine are now so closely associated with the health and happiness of the community that they can no longer be considered apart from pathology and therapeutics, but all these must be considered as an independent whole. For just as general medicine contains specialties, a complete comprehension of which would require twenty-five or thirty years to master, so the dentist has undertaken a specialty the complete comprehension of which would require ten or twelve years. This preliminary training is not feasible. By the time a man has studied ten or twelve years in college he will be so old that the enthusiasm of youth will be apt to be lacking and so it would be difficult for him to build up a practice. There should be, in my opinion, a bachelor's degree of medicine that *per se* would not allow any man to practice medicine, but from which he could go on to the special doctor's degree to which he would effectively confine his efforts.

Dr. F. B. Moorehead, Chicago: The discussion of any educational subject is of vital human interest and no set of men can ever determine the ultimate policy of any educational system, simply because it is a matter of evolution. This whole question that we are facing to-day in the matter of dental and medical education is simply a sign of the times. As man expands in thought and usefulness in the world, he is most surely going to demand a different type of training, and that is what this means. The question of dental education is a live subject to-day, because we are now facing a fact and not a theory. The physician and dentist have both awakened to the fact that the mouth is more important than it was thought in the past, and, therefore, the dentist must face and solve some serious problems. This calls for a different type of dental student. How to make that different type is an exceedingly difficult problem. We must educate enough dentists to care for the people and at the same time we must change from the kind of education we have given in the past and make the dental student a broader man. One step in that direction is the four-year course which I am convinced is sure to come. The first year in the four-year course should be a predental year in the university. The university method of study; the university enthusiasm and spirit will give the student a bigger and better perspective. This is the type we must have for the dentist of to-morrow. One cannot get away from the fact that, as much as we value medical training, the man who is to be a good dentist must be a good mechanic, because if he is not he cannot make his patients comfortable, and unless he makes his patients comfortable he is not serving them properly. The man who is uncomfortable is physically and mentally unfit. So we cannot lose sight of the fact that we must make mechanical dentists while developing the man of parts to take care of the medical side of dental practice.

Dr. Arthur D. Black, Chicago: I think Dr. Brown has presented the consensus of opinion of a great many physicians and dentists as to the general proposition of the future of our educational system in medicine and dentistry, and the relationship which will probably exist between dentistry and the other specialties on the one hand, and a general medical education on the other. By the process of evolution we are gradually coming to the point where, whether it is taught in the medical school or in the dental school, all men who practice medicine and the specialties of medicine must have the same foundation education. It is certainly as important that the dentist know as much of general medicine as the man who is practicing any other specialty of medicine. That it will be a great many years before the dental specialist gets that foundation in the medical school, I am quite thoroughly satisfied. The greatest problem that we have from the point of view of dental education is that of developing a different type of men in the dental school, men who will enter with the idea that they will have to study and master physiologic and pathologic problems as a basis for their technical service. In the school with which I am connected we are endeavoring to develop this type under the conditions which now necessarily exist by shifting more of those subjects which require hard study into our freshman year and diminishing the amount of technical work required during that year. We hope to impress the student with the fact that he must learn to study if he ever gets the dental degree, and at the same time we are eliminating in the freshman year a lot of men who will not study. Doubtless the higher entrance requirement, especially if this consists of a prescribed course of a year in college, will be of material aid, both in the extra year's work and the college associations. This is a problem which many men interested in college work are considering at present; that we should prescribe, previous to admission into the dental school, not only a high-school education, but definite instruction in certain branches which the academic department is better qualified to give than is the dental school.

There is, however, another question to be considered in this connection. While the dental school must develop men who will be able to solve the more complex problems involved in the relationship of mouth conditions to general health, they cannot, on the other hand overlook the greatly increasing demand for the ordinary care of the teeth. The wave of public education in oral hygiene has brought such an increased demand for the most ordinary dental service that we cannot go so fast in this matter of advancing dental schools that we will materially reduce the number of graduates and thus not provide sufficient men for the ordinary dental service.

Dr. Eugene S. Talbot, Chicago: At the time this section was established few graduates of medicine were practicing dentistry. Indeed very few were graduates in dentistry, as compared with those practicing without a degree. The friendly relations between dentistry and medicine, and between graduates of dentistry and non-graduates did not then exist. The medical profession on the other hand has always shown the greatest respect for our specialty. This is no doubt due to the fact that physicians realize that each branch of medicine has gradually advanced from small beginnings, requiring many years to reach the present state of evolution. They are willing and glad to help the youngest branch of medicine in its rise to a higher position. The Section on Stomatology has from year to year endeavored to represent the best material in the dental profession. We had been organized only a few years when we found that some of the ablest men practicing dentistry had not the medical degree, which was then necessary for membership in the A. M. A. We petitioned the general body and they immediately changed the constitution and by-laws so that practitioners of dentistry, holding the degree of D.D.S. and belonging to their state and local dental societies, could become "dental members" enjoying all the privileges of regular medical members. Again the medical profession came to our rescue and gave us a helping hand. Dental members have been stimulated to a higher sense of their relation to medicine. On the other hand, at nearly every meeting the names of physicians and surgeons are on the program. At present physicians are invited to read papers in dental societies and dentists have read papers at medical gatherings. There is no doubt that, in the future, some medical societies will recognize the dental degree for all that it implies, just as they now recognize other specialties in medicine. Recently a mutual ground between dentistry and medicine has been found, for which this section stands and which neither dentistry nor medicine are in themselves qualified to practice or teach. Those who will be the future successful practitioners of stomatology must be well grounded in the general principles of medicine. The practitioner of medicine has already begun to recognize those specialists who are abreast of the times with regard to mouth infection as a source of systemic disease. The physician will soon seek those who are competent to assist him in making an exact diagnosis. Dentists who wish to be successful in the future must thoroughly educate themselves in both medicine and dentistry. The Council on Medical Education should discourage medical schools from conferring medical degrees on dentists who have not taken the prescribed medical course.

Dr. W. C. Fisher, New York: Dr. Brown's suggestion as to the establishment of the B.M. degree is a good one. I read a paper last year entitled, "The Need of a New Degree, Bachelor of Medicine." I simply gave it as a suggestion at that time, and backed up my statements by those of Dr. Bevan of the Council on Medical Education of this Association, in which he stated that too much time was being wasted in preliminary preparation before men entered the medical schools; that we could not turn out competent medical men in twenty-nine or thirty years with the present restrictions, and that some new scheme would have to be devised whereby men could go out on their life work earlier. Professor Lowell of Harvard has said that instead of demanding the Bachelor of Arts degree before entrance to medical schools it would be better if we would incorporate some of these studies in the course leading to the Bachelor of Science degree and take one year from the four-year course, instead of spending a couple of years in studies that did not particularly relate to medical education. The man who has an excellent preparatory school education, and that does not mean two years in college, is qualified to undertake the study of the sciences of medicine and dentistry. When we speak of getting better men I am in favor of that, but I am opposed to anything that makes it so late in life before a man can acquire that degree which entitles him to go forth into the world and earn his livelihood.

Dr. G. V. I. Brown, Milwaukee, Wis.: We have been discussing subjects that my paper relates to ever since the meeting opened, and it is clear to me that, in the settlement of this question, the time element alone will not do it, but it is equally clear to me that we should not make any step in this direction until we know best what to do.

CONTINUOUS PAINLESS RENAL HEMORRHAGE AND ITS TREATMENT *

WILLIAM M. SPITZER, M.D.
DENVER

The selection of the title for this paper has been made with the purpose in view of excluding all other conditions having hematuria as an accompanying symptom, and limiting the name to those cases in which there is constant and continuous bleeding from the kidney over a considerable period of time unaccompanied by pain except such as could easily be explained by the plugging of a ureter by a blood-clot. Objection might be had to the word "continuous," for in many cases the bleeding stops either spontaneously or after the administration of medicines or of serum, or as the result of mechanical therapy directed to the kidney pelvis. The bleeding may start again and continue for weeks or months, during which time blood in varying amounts may be recognized macroscopically in the urine. The term "essential renal hematuria" is in my opinion a proper name for this condition, because it is from the kidney substance that the bleeding takes place. This name, however, should be applied only to those cases in which absolutely nothing pathologic other than blood appears in the urine, and where no lesion can be demonstrated by a competent urologist. When epithelium from the tubules or the pelvis, or when pus, micro-organisms or crystals of any type are found in the urine with the blood, or when with the Roentgen ray or by palpation a tumor or foreign body be diagnosed in this organ, or when intermittent or chronic hydronephrosis is found or suspected, it would be manifestly wrong to call such a condition essential renal hematuria just because blood is present in the urine. I shall have occasion later to refer in a more detailed manner to the subject of differentiating this condition from others in which bleeding exists.

The literature on this subject is too voluminous to review at length. To those who are interested I may refer to Kretschmer's article,[1] which brings the bibliography up to 1907, and White's paper,[2] dated 1910. The bibliography since these reviews were published is also quite extensive, and I shall only give the gist of the opinions expressed therein.

Pathologists are in apparent accord that the lesions found in renal hematuria are confined mostly to the glomeruli, and the bleeding has therefore been attributed to a glomerulonephritis. The changes are briefly as follows: while most of the glomeruli are normal, a few show absence of some of the endothelial cells lining Bowman's capsule, while others show hyaline degeneration, and some have undergone fibrosis. Kidneys that had bled for a long time present more advanced changes of the same kind with a beginning fibrosis of the intertubular tissue, in other words an interstitial nephritis—*identically the same changes which are found in kidneys which have been passively congested for some time.*

Senator[3] cites a case in which he could find no lesion of the kidney either macroscopically or microscopically, and believes the condition to be a renal hemophilia. The general opinion, however, is that if these kidneys were scrutinized more carefully the changes described above would have been found.

Much has been written to show that hemorrhage from the kidney is fairly common in lesions of that organ. Elsner[4] tabulates the cases in which blood was found in the urine as follows: Chronic tubal nephritis, 33 per cent.; acute tubal nephritis, 100 per cent.; *secondary congested kidney, 100 per cent.;* chronic interstitial nephritis, 14 per cent. In the same article he cites cases of profuse hemorrhage with no symptoms and no findings in the urine which would indicate nephritis, and yet these after a long time (in one case five years) presented symptoms or urinary findings which are expected in Bright's disease. In the vast majority of these cases the blood was microscopic, and they, therefore, cannot be dignified with the term "hematuria."

The question naturally arises, Why is there such profuse bleeding in essential renal hematuria when pathologic changes are so slight, whereas in the kidneys of patients who have succumbed to nephritis in which the lesions were a hundred times worse there had been no hematuria? Are these pathologic changes the cause of hematuria as is generally thought, or are they the result of the process which causes the bleeding? In my humble opinion the prime cause is a chronic passive congestion. Although positive proof of this assertion is still lacking, I shall essay to bring forth some facts which tend to favor this view.

---

It is not uncommon to find blood in microscopic quantities in the urine from a kidney which is out of position, particularly when hydronephrosis is present. Occasionally even free bleeding is present. When the kidney is fixed properly in position this bleeding ceases. It is therefore fair to presume that the hemorrhage was due to a passive congestion, because while the inflowing blood-supply was not interfered with, the outflow was impaired. This would naturally come to pass in certain positions of the kidney because the caliber of the vein is more easily reduced in size than that of its companion artery for the following reasons:

1. Because its wall is thinner than that of the artery.
2. The pressure behind the inflow is many times greater than in the renal vein.
3. Because there are as a rule multiple renal arteries, while multiple renal veins are the exception.

If this passive congestion lasts a certain length of time, we shall find the identical changes that are seen in kidneys removed for essential renal hematuria. What more natural therefore than to assume that the cause of essential renal hematuria is a passive congestion?

Another reason for our belief is that these cases of essential renal hematuria cease to bleed spontaneously, and remain apparently well for varying periods, often never to recur. How may we account for this except for the explanation that the kidney after being twisted on a short pedicle so as to narrow the caliber of the vein subsequently resumes its proper position? The outflow of blood being no longer obstructed, the passive congestion clears up and the bleeding stops. In a week, a month, a year, the kidney may for some reason again be out of position, passive congestion once more occurs, and bleeding ensues.

We can thus account for the fact that Senator and others found no microscopic changes in some of these excised kidneys, while other observers have frequently found the glomerulonephritis previously described. If the kidney started to bleed as soon as it became congested and was removed before the pathologic changes could occur, it would be of course perfectly normal to the naked eye and under the microscope. In those cases, however, in which the passive congestion had continued over a longer period before removal, we would find this glomerulonephritis. If the kidneys were taken out at a still later stage we would probably find all the changes that accompany a chronic interstitial nephritis.

It seems to me that a passive congestion of one kidney can be accounted for only by a twisted short pedicle, for I can conceive of no other way, barring outside pressure on the pedicle, that would give rise to this condition. Several other observations have led me to believe that a twisted pedicle is the cause of this condition. In stereoscopic pictures of the collargol-filled kidney pelvis the organ occupies normally a certain fixed position, with the pelvis directed downward, inward and forward toward the ureteropelvic junction, while in cases in which the kidney cannot be called loose, but is nevertheless giving trouble, we have found its position so changed that the convex border instead of being almost parallel to the spinal column, is nearly at a right angle to the spine, as shown by the direction of the pelvis. In other cases again, particularly the one I recall to mind, in which a beginning hydronephrosis existed with blood in the urine, the kidney was so placed that its convex border presented toward the abdominal wall. The patient was cured by fixing the kidney, which was not loose, in its proper position.

Another argument: In cases of hydronephrosis with concomitant bleeding the latter symptom was arrested by simply fixing the kidney properly; and cases of essential renal hematuria in which no hydronephrosis was present have been cured by fixation.

The necessity of differentiating this condition from others accompanied by renal bleeding is quite apparent, but not always so easy. The microscope must show red blood-corpuscles unaccompanied by pus, micro-organisms, casts or epithelium from the kidney or its pelvis. The bladder must be free of disease, the ureter mouths normal, the flow from the ureter catheters normal, the kidney must be impalpable, or if palpable no larger than normal and it must present no irregularities to the hand. The Roentgen ray must show the kidney clearly when a pyelogram is made, and the kidney pelvis must be normal in shape and size. If the contents of the kidney pelvis exceed 10 c.c.[5] I do not consider it normal. With these restrictions we can exclude renal tuberculosis, stone, abscess, hydronephrosis and the commoner conditions in which hemorrhage occurs.

In tumors of the pelvis, by the time bleeding is continuous, one would expect epithelium in large quantities from the pelvis, together with débris from the constantly degenerating neoplasm. Continuous hemorrhage is extremely rare in tumors of the kidney until the enlarged growth has attained such a size as to be palpable.[6] Pyelitis will show besides red corpuscles other elements in large numbers in the segregated urine. Nephritis presents well-known symptoms or urinary findings which make this condition recognizable. *Besides a true nephritis cannot be one-sided.*

A diagnosis of essential renal hematuria having been established, the question arises as to its proper treatment. Ordinarily we should keep the patient under observation unless the anemia begins to give grave concern. Many of these patients never become anemic. In the meantime we may try the injection of blood-serum, a rest in bed for a short time, and a properly fitted lower abdominal corset. As to the injection of epinephrin into the kidney pelvis,[7] I consider this procedure more of a diagnostic than a therapeutic measure. If the bleeding arises from the pelvis the urine should be free from blood, or at least clearer for a short time following the injection, although it should not (theoretically) affect the bleeding in essential renal hematuria. In the three cases in which I have tried epinephrin the result was nil.

If the anemia progresses in spite of these procedures it is time to consider surgical intervention. One must, however, think long and arduously before daring to operate, and when operation is finally decided on, nephrectomy should be the last thought.

Years ago, before the advent of the present diagnostic facilities, the kidney was bisected at the operating table in order to determine whether stone or tumor was present. If neither was found the organ was securely sewed together. To the surprise of the operator the bleeding from the kidney stopped,

7. Suggested by Kretschmer, with report of case in which bleeding was stopped, The Journal, A. M. A., July 5, 1913, p. 17.

we can refuse to call these conditions cases of essential hematuria when they are narrowed down. It is the kidney substance itself that is bleeding. It is a cloak for our ignorance to call it idiopathic renal hematuria, but it is not so to call it essential renal hematuria. Dr. Cabot doubts that the changes can be the same in these kidneys as those we find in chronic interstitial nephritis. They will be the same eventually. If a chronic passive congestion of the kidney exists, the same changes that I have described will be found, and after that a round-cell infiltration and finally an intertubular fibrosis, and thus, eventually, all the changes of chronic interstitial nephritis. Dr. Cabot also spoke of varix of the papilla. The reason I did not mention it was that I was afraid to. Harry Fenwick has described six cases and Dr. Cabot has described one. I do not see how it could be demonstrated microscopically after the kidney was excised. It may be it can be demonstrated macroscopically while operating. Lately there have been no cases of varix of the papilla reported. Dr. Squires speaks of a case of tumor of the kidney with accompanying hemorrhage, in which there was a low output of phthalein. This is as it should be. If careful roentgenograms had been taken in his case, I do not doubt that the diagnosis of tumor would have been made before the patient was operated on.

EXTRAPERITONEAL RUPTURE OF THE BLADDER

ITS SURGICAL MANAGEMENT *

EUGENE FULLER, M.D.

NEW YORK

Extraperitoneal rupture of the bladder, for a serious injury, has received little specialized study or attention, and when this can be said of a surgical condition of such magnitude it follows almost as a matter of course that its management has been, as a rule, inefficient and unsatisfactory. Some may criticize this statement on the ground that hospital statistics show that a large percentage of patients with such injuries are at present discharged from the hospital alive and with the record "recovered." Still, if one will take the trouble to investigate these patients so discharged, it will be found that almost all of them have recovered only sufficiently to be discharged from hospital, and that most of them have been left invalided—the majority, severely so.

Peritoneal rupture, on the contrary, has been carefully studied, and the surgery applied to it has been radical and eminently satisfactory. Severe violence directed against the suprapubic or perineal region may result in extraperitoneal rupture. When violence is simultaneously exerted in both these directions, the bladder has small chance of escaping severe damage. The worst cases of extraperitoneal rupture are those associated with fracture of the pelvis. In many such cases violence has been severe enough to cause general destruction and to make death inevitable. In these extreme instances surgery, at its best, may be ineffectual. It is in the cases uncomplicated by pelvic fracture that surgery has a chance to show its efficiency.

Extraperitoneal rupture generally occurs in the region of the trigonum; less frequently above, under the space of Retzius, and occasionally at the side of the vesical neck. In most instances the injury consists of one tear, less frequently of two, and occasionally of even more. Multiple ruptures usually occur in connection with fracture of the pelvis, and some of them are in the nature of punctures caused by the sharp ends of the fractured bone. If a rupture is small and perhaps incomplete, the amount of urine extravasated may be correspondingly slight, the result being simply a circumscribed area of involvement. A case such as this, treated expectantly, can leave the patient with nothing more than a corresponding area of pericystic sclerosis. The symptoms arising from such sclerosis may be slight or severe, according to the extent and position of the lesion. In the great majority of cases, however, owing to the volume of the extravasation or to a complicating secondary infection, expectant treatment invites a fatal termination. Following such injury, the extravasated fluid tends as it increases in amount—owing to a continuance of vesical distention or to pus formation from secondary infection—rapidly to extend itself, so that after the extravesical space about the site of the rupture is filled, active burrowing follows. The directions which can be taken by such burrowings are various. One point, however, seems from my experience to be reasonably assured, and that is that the most dependent part of the extravesical space—in other words, the postprostatic area in which the seminal vesicles lie—always becomes involved; primarily, when the extravesical rupture is, as is usual, at the base of the organ and secondarily, when it is elsewhere. This is a point of the utmost importance to be kept in mind, as will be seen in considering surgical treatment.

Further burrowings point outside the pelvis. They may extend behind the peritoneum—sufficiently, perhaps, to involve the perinephritic region on one or both sides—or they may mount upward, filling the space of Retzius in the middle, or the inguinal regions to either side. The extension above the space of Retzius may result in a marked hypogastric tumefaction, liable to be mistaken for an overdistended bladder. Or, following extrapelvic deviations of the pelvic fascia, the burrowing may invade the thigh, passing out of the pelvis under Poupart's ligament, generally externally to the internal iliac vessels; or it may reach the scrotum, following along and externally to the structures occupying the inguinal canal. The buttocks can be invaded, the paths being via the obturator or the great sacrosciatic foramens. These last paths, however, are rarely taken, as they are narrow and devious. Extravasations can break through the pelvic fascia into the ischiorectal space, the perineum and elsewhere, but the assumption of such directions is not to be expected unless the trauma causing the bladder rent likewise breaks down other structures which would otherwise serve as natural barriers.

There are no strikingly characteristic clinical symptoms associated with extraperitoneal vesical rupture, and it is on this account that often the injury remains undetected until inflammatory changes or burrowings in connection with the extravasation attract attention. Hematuria is present after the accident, perhaps to such an extent as to fill the bladder with clot; or it may be so slight as to cause no noticeable discoloration. When the bleeding is so slight as not to cause the formation of clot, and when the laceration does not involve the vesical neck, there is not apt to be retention. There is always some pain on urination, and this may be severe. The pain, however, associated with other parts which have been injured by the

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

traumatism responsible also for the bladder injury, may be so prominent as to divert attention, thus causing the discomfort connected with urination to escape observation. There is apt to be febrile disturbance, generally marked. As extravasation progressively develops, attendant symptoms arise, and it is these secondary symptoms, as stated, which frequently first lead to a realization on the part of the surgeon of existing conditions.

Diagnostic considerations as regards extraperitoneal vesical rupture vary greatly in accordance with the time which has elapsed after the accident before surgical aid can be rendered. When a surgeon sees a case promptly, the differential diagnosis between anuria, intraperitoneal rupture and extraperitoneal rupture is most important. When there has been considerable delay, time itself, for better or worse, has generally solved these questions, but left in all probability others. When a case indicating bladder injury is seen promptly, the patient should be instructed to urinate. If he can do so naturally and the urine is free from blood, the chance is that there has been no vesical injury, and expectant treatment, as far as the bladder is concerned, is warranted. If he cannot urinate, a sterile catheter should be passed. If no urine and no blood is thereby revealed, the probability of anuria due to shock is justified. The abdomen, however, should be carefully watched, and if, at the end of a brief interval, on a second introduction of the catheter no urine should be found, a measured amount of sterile normal saline solution should be injected into the bladder. If the volume injected is caught in the return flow, well and good. If not, the abdomen should be promptly opened and an intraperitoneal rent looked for and closed, if found. If there be no intraperitoneal injury, inspection should then be made to find if there exists any evidence intra-abdominally of extraperitoneal vesical injury.

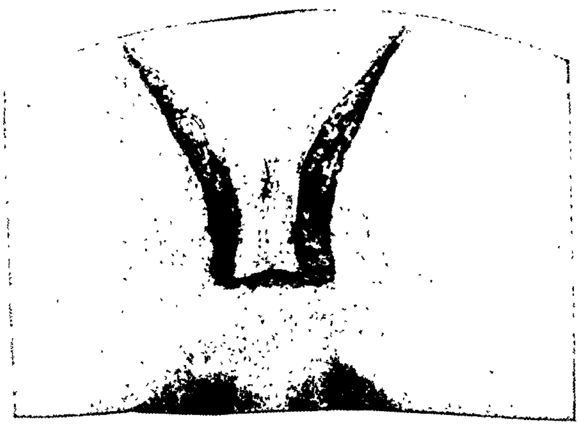

Fig. 1.—Line of incision.

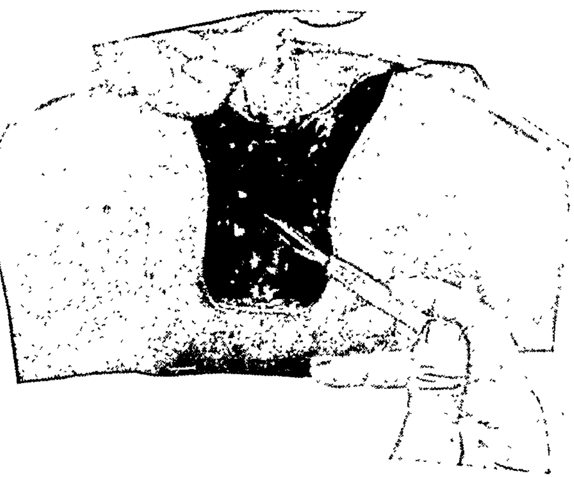

Fig. 2.—Perineal dissection.

To aid in this inspection, in case there should be no evidence, a catheter can be introduced and the distention of the bladder watched as fluid is injected. The abdominal wound should then be closed and the bladder opened suprapubically and drained. Such prompt drainage may anticipate any extraperitoneal extravasation, allow the bladder to heal, and obviate a secondary operation such as will be necessary should there be any marked degree of extravasation. If the bladder contain blood clot, or if there be retention due to an involvement by the trauma of the bladder neck or deep urethra, then suprapubic cystotomy should be promptly performed. The bladder, on being opened, should be emptied and inspected, to locate injury. If there be then any indication of rupture involving the peritoneum, the abdomen should be opened as a secondary step in the primary operative procedure, and such a rent closed. In any event, suprapubic vesical drainage should be established. If suprapubic cystotomy discloses extravesical rupture and there is good reason to believe that the bladder has been opened before urinary extravasation to any degree has had time to take place, nothing further should be done. After such operation it may be advisable—even in case there be doubt regarding the question of extravasation—to delay operating to insure extravesical drainage until symptoms develop indicating the necessity for such further procedure.

It is the cases of extraperitoneal vesical rupture that have not had the benefit of prompt surgery immediately following injury—a prophylaxis, as it were, against urinary extravasation—which especially deserve notice, as they represent the large majority. Before considering the question of how these should be surgically treated, it may be well to remark on the inefficient treatment so generally employed, for it is from the study of bad results that good ones can be appreciated.

In most instances in which extravasation has not burrowed sufficiently to produce external manifestations, it will be found that the bladder has been opened perineally or suprapubically, or perhaps in both directions. When burrowing has been extensive enough to cause surface evidence or much localized pain, an incision into such part or direction is common, followed by the liberation of pent-up fluid and the maintenance of drainage. Although late cystotomy does little and perhaps no good, incision into the area involved by the extension of extravasation is very beneficial in that it probably saves life. Still, its fault is that it does not cure. This is because such incision only partially drains the area. Another error into which those cutting into such burrowings may fall is observed in connection with cases in which the burrowings have been sufficiently extensive to point outside the pelvis, far from its original source. When such a pus cavity is opened, the false inference may be drawn that a nearby part is the source of suppuration and consequently requires surgical removal. As an illustration, the head of the femur has been resected, the suppurative process having in reality burrowed out of the pelvis by way of the great sacrosciatic foramen; or a piece of the sacrum has been chiseled off, on the supposition that disease there was the original cause.

In a paper[1] which I read in 1902 and which represented my early surgical experience, I made the following remarks:

> The surgical management of suppuration in this part or elsewhere lies in the establishment of free drainage. In order that drainage be free, it must be dependent. As the pelvic cavity is deep, the surgical problem of effecting dependent drainage arises. . . . In each individual case there are two surgical principles to be determined in connection with the establishment of the drainage: first, the location of the dependent pocket of suppuration, and, second, the dissection to reach that pocket. . . . No dependent dissection should be attempted till the pocket has been located. . . .

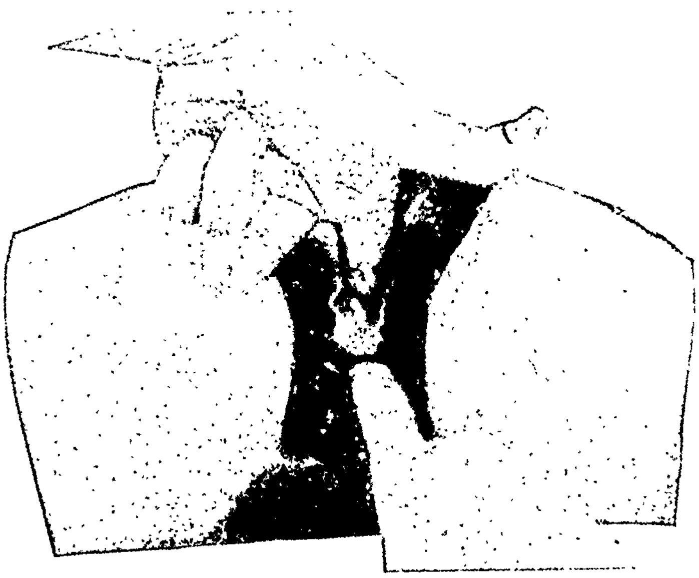

Fig. 3.—Separation from the rectal wall.

> The second step in the surgical procedure is the dependent dissection. This dissection should open a perineal path and expose the lymph space between the prostatic capsule and the rectum, the urethra being left intact. In making this dissection, the dorsal position and the Zuckerkandl incision can be employed; but what is far superior is the knee-breast position and the incision which I devised to expose the seminal vesicles and the prostate, a description of which has been published in The Journal of the American Medical Association, May 4, 1901.

This early opinion, though thoroughly sound, I have since seen fit to modify as regards procedure, in that I now make the second step the first, while the original first step becomes the second. This change simplifies matters and avoids exposing the patient to what often resulted in a needless degree of dissection in locating the pocket in connection with the original first step of the operation. As all these extravasations tend speedily to reach the most dependent extravesical space, that space should first be opened. It will then be found a much simpler matter to trace with the finger or probe the track of the burrowing from its dependent position to its limit of extension, than was the vice versa original procedure. When the limit of extension is located, an external incision can be made down on the end of a probe and drainage tubes introduced. It may be that burrowings have taken place in more than one direction, in which event more than one external connecting incision will be necessary. Drainage tubes should be serrated and of sufficient length to pass in at the external connecting incision and out at the entrance to the dependent incision.

The accompanying photographs illustrate the performance of the dependent dissection. As the seminal vesicles in these cases are embedded by infiltrate, it is wise to open them just as would be done in the performance of a regular seminal vesiculotomy. The patient is in the knee-chest position.

Figure 1 shows the line of incision. In this photograph, although the depth of the incision is still superficial, the marked tendency to retraction of the tissues is clearly evident. This tendency to retraction, intensified by the position of the patient, is an element of great aid to the operator. The converging cuts on either side of the rectum are made long so that the rectum can freely retract as the perineal dissection liberates it from its natural anchorage.

Figure 2 indicates the method of perineal dissection. Note the marked retraction of the rectal structures, the lower rectal flap having already retracted fully two inches. This retraction is sufficient to expose the prostate on lifting the rectal flap, making that organ a superficial rather than a deep-lying structure. In making this dissection, the forefinger of the operator's left hand is maintained in the rectum to serve as a guide while the dissection progresses. While so operating, the side rather than the blade of the scalpel is used, so as not to cut into the muscular structure of the perineum, the path of dissection lying just outside the muscular perineal body and inside the perineal fascia. By so doing, and by starting the transverse flap well below the margin of the anus, the rectal sphincter and the blood-vessels encircling that organ escape injury. In fact, so little injury is done to blood-vessels that it is exceptional when it is found necessary to ligate a single vessel through the performance of the entire operation. As the dissection proceeds around the perineal body, that structure tends of itself to retract downward. The fascia propria of the pelvis, with its median raphé, is then exposed, and when this is cut through the bursal space separating the rectum from the prostatic body is entered.

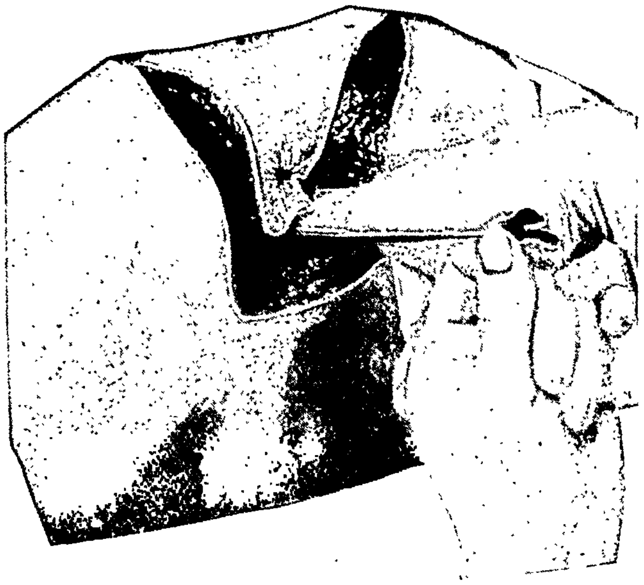

Fig. 4.—Placing the grooved director.

Figure 3 shows the next step in the operation, the separation of the rectal wall from the underlying prostate, the seminal vesicles and the bladder floor. After the fascia propria of the pelvis has been divided, the scalpel is put aside and the right forefinger of the operator is introduced into the bursal space just mentioned, and the process of separating the rectal wall from the prostate and seminal vesicles by digital manipulation is undertaken. In accomplishing this, the right finger-tip should be bent down to guard against perforation of the rectal wall, while the left forefinger is still maintained in the bowel as an aid in the same direction; for should the right finger impinge too closely on the bowel wall in accomplishing its separation, the left finger gives the operator immediate warning. In the performance of this digital separation it may be that fibrous bands are encountered, too dense for separation by the finger-tip. If such is the case, the scalpel guided by a director can be introduced to cut the band, after which the digital separation is resumed.

---

[1] Fuller, Eugene: Drainage of Extravesical and Extraperitoneal Suppuration of the Male Pelvis, The Journal A. M. A., Oct. 25, 1902, p. 1021.

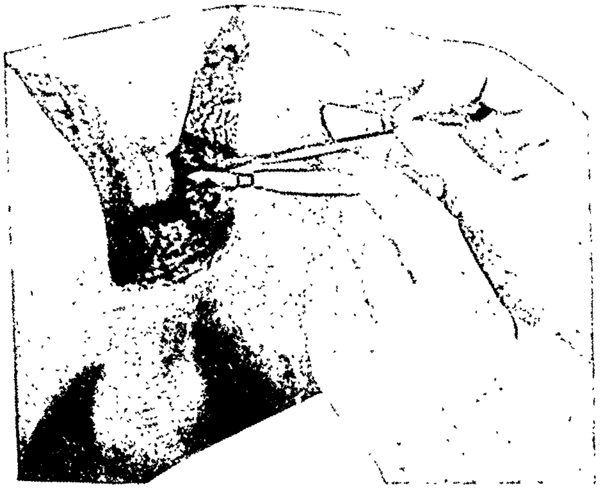

Fig. 5.—Passing the knife.

Figure 4 illustrates the putting in place of the grooved director under the guidance of the operator's right forefinger. After the rectal wall has been detached from the underlying seminal vesicles, the operator places his right forefinger-tip on the apex of a seminal vesicle (in the photograph, it is the apex of the right organ), and maintains the finger-tip in that position, while with the left hand the grooved director is passed under and along the right forefinger till its point reaches the apex of the seminal vesicle under the right finger-tip. In this position the director is firmly held while the right forefinger is withdrawn.

Figure 5 shows the next step in the operation, which is the passing of the knife along the groove of the director. After the knife reaches the apex of the seminal vesicle at the point where the end of the grooved director is fixed, its shaft is lowered so that the belly of the blade lies against the seminal vesicle, and a cut of an inch and a quarter to an inch and a half is made longitudinally into the seminal vesicle so as to lay that organ open its entire length. Often the first cut may not be deep enough to accomplish its purpose. If a digital examination shows the cut to be incomplete, the director should be replaced and a second cut made in the line of the first. Sometimes, especially in sclerous cases, three or more cuttings may be required before a thorough opening of the seminal vesicle has been accomplished. Should it be desired to open the floor of the bladder for drainage, the end of the director should be placed against the wall at a point midway between the seminal vesicles and far enough back to be in a line with their apices. The knife should then be slipped along the groove and the bladder wall perforated, after which the director should be immediately slipped into the bladder and maintained there to guide the introduction of a drainage tube.

Figure 6 shows the method of packing the cavities of the seminal vesicles and the deep limits of the dissection. Two strips of gauze are employed, one for each side. Here the packing is being introduced into the right opened seminal vesicle, the right forefinger of the operator being maintained in the opening to crowd in and arrange the placing of the gauze as it is being pushed in by the operator's left hand, aided by a blunt-ended clamp. In placing the packing, a space should be left between it and the rectal wall for the drainage tubes.

Figure 7 shows the two drainage tubes in place above the packing, the lower portion of the dissected flap having been fastened in place by lateral sutures.

Figure 8 shows the completed operation previous to the placing of the dressing. The two ends of the gauze packing are left protruding, to facilitate removal. Safety pins have been passed through the tube ends, and to these have been attached strips of adhesive plaster, so as to guard against a premature slipping out of the tubes.

The following clinical reports serve to illustrate the surgical procedure advocated in cases coming under observation long after the original injury:

CASE 1.—Man, aged 23, on entering the City Hospital could not walk without support, nor could he void urine. All the urine leaked away through a perineal sinus. There was constant and severe pain in the region of the pelvis. Several months before, while working in a mine, his pelvis had been caught between two cars. Retention followed the pelvic injury. He was sent to a local hospital, where a perineal opening was made, and it was out of that opening that the urine was passing when he entered the City Hospital. Roentgenoscopy revealed that there had been a fracture of the pelvis. The injury had also caused thorough disorganization of the deep urethra, so that complete occlusion had resulted. Rectal examination showed marked tumefaction of the postprostatic tissues, and any pressure there caused extreme pain. The patient was put in the knee-chest position and the seminal vesiculotomy dissection was made. Before this dissection had extended beyond the prostate, the anterior limit of the dependent area of extraperitoneal extravasation was opened, and when completed a large chamber was exposed occupying the entire postprostatic space. Com-

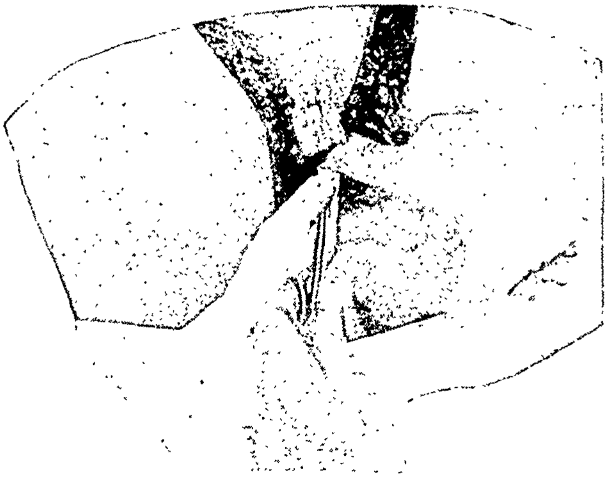

Fig. 6.—Placing the packing.

municating with this chamber was an opening through the trigonum sufficiently large to admit the forefinger. To the right of the vesicle neck, the chamber extended upward into the space of Retzius. A suprapubic counter-opening was consequently made, and a connecting chamber occupying the space of Retzius was thereby exposed, and another vesical rent found connecting the bladder cavity directly with the space of Retzius. From the space of Retzius, the burrowing had extended to the left under Poupart's ligament and into the upper thigh. An opening was consequently made into the upper thigh so that a drainage tube from the suprapubic opening could be there passed out. A suprapubic drainage tube was also passed through the space of Retzius to the right of the vesical neck, through the postprostatic space, and out at the base of the perineal dissection. Another good-sized tube was passed along the perineal incision and into the bladder through the rent in the trigonum. This was for vesical drainage. The operation was followed by marked relief.

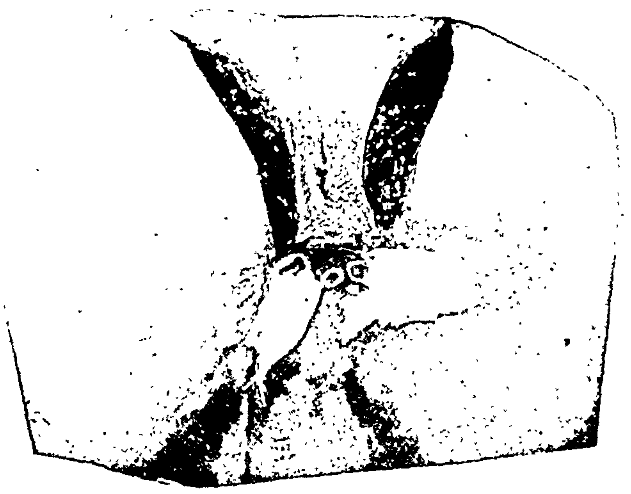

Fig. 7.—Drainage tubes and packing.

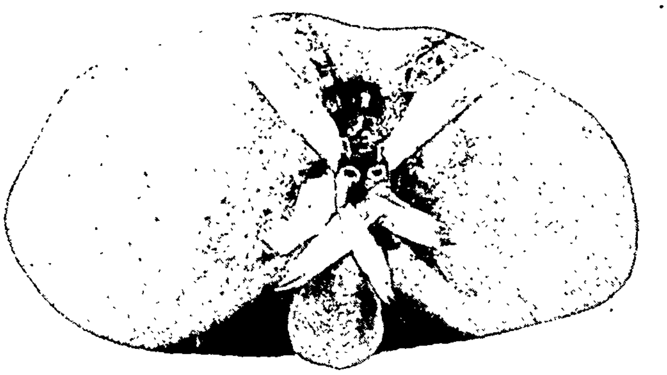

Fig. 8.—*The completed operation.*

Two months after the first operation the deep urethra was resected and made pervious. The patient now—four months after the first operation—is about, using a cane, in comparative comfort. The suprapubic opening into the space of Retzius has not as yet been allowed to close, so as to afford a vent in case of persisting suppuration. The flow of urine, likewise, has not yet been diverted from the perineum to the urethra. The perineal opening can, however, be closed by a slight plastic operation whenever it may be deemed advisable.

Case 2.—A man, aged 31, entered the City Hospital with a history that two years before a log had fallen on him, causing rupture of the bladder, together with laceration of the deep urethra. Suprapubic cystotomy had, at the time, been performed. Eight months later, a perineal section had been performed to rid the patient of traumatic stricture formation and to avert threatened retention. His chief complaint on entering the City Hospital was impotence, which had been complete ever since the accident. On this account, his wife had left him. There was also marked pain in the sacral region after much exertion, together with loss of force to the stream on urination. Rectal feel showed marked infiltration and tumefaction of the postprostatic tissues, digital pressure causing severe pain. There was still a marked traumatic stricture involving the deep urethra. Before the accident the patient had been normal and vigorous sexually, and there was no antecedent history of gonorrhea.

The opinion being held that the postprostatic tumefaction was due to urinary extravasation, the patient was put in the knee-chest position, and the seminal vesiculotomy dissection employed. A burrowing extravasation cavity, in which lay both seminal vesicles, was opened. This cavity was found to communicate with the bladder by way of a rupture through the middle of the trigonum. This rupture was large enough to admit the tip of the forefinger. The extravasation had not burrowed beyond the confines of the postprostatic space. The involvement of the seminal vesicles evidently accounted for the impotence. Both these organs were opened, as in an ordinary seminal vesiculotomy, and their cavities, as well as that of the extravasated area, packed. A perineal tube for urine drainage was passed into the bladder through the opening caused by the rupture.

Two months after this operation, the deep urethral stricture was resected. This patient is now completely well, has regained his sexual stamina, and is at work as a laborer.

Case 3.—A man, aged 40, came to hospital with the history that seventeen years before he had fallen fifteen feet, striking his sacrum against a wheel. Before the accident he had been strong, and up to that time he had never had sexual intercourse. After the accident he was in bed for a long time, and had great difficulty with urination, together with pain, but as the accident had occurred seventeen years before it was impossible to obtain exact clinical data. Four years after the accident he married and had one child. He had never been well since the accident, owing to severe sacral and suprapubic pains, increased on exertion. These pains were often accompanied by chills or chilly sensations. The sexual function had never been strong since marriage, and for many years he had not indulged in coitus at all, owing to the fact that the act served to exacerbate his pains and chills. At present he had no complaint regarding urination, and the urine was normal. He had a great dread of urethral instrumentation, as such treatment caused him much after-suffering from an exacerbation of his symptoms. Neurasthenic symptoms were marked. In fact, neurasthenia had been the usual diagnosis given to account for the symptoms. Rectal feel showed the postprostatic space filled with scar tissue which involved both seminal vesicles. Digital pressure against this region provoked great pain and could not be tolerated. There was no stricture. The cystoscope showed little except that in the region of the trigonum the blood-vessels were enlarged and irregular. There were also in that area patches of scar tissue.

The patient was put in the knee-chest position and the seminal vesiculotomy dissection employed. In this case no actual extravasation cavity was found, probably owing to the fact that the accident had been so long ago; but the dense cicatrix was cut through, the floor of the bladder liberated, and also the seminal vesicles, after which both these organs were opened. The space was packed and drained.

Complete recovery, with relief of all symptoms, followed.

252 Lexington Avenue.

ABSTRACT OF DISCUSSION

Dr. A. G. Rytina, Baltimore: In connection with Dr. Fuller's paper I will mention a case that is perhaps a surgical curiosity, and I report it to find out if any one has seen such a case. About six or eight months ago a young man entered the Physicians and Surgeons' Dispensary complaining of burning on urination. While one of my assistants was introducing the cystoscope into the posterior urethra the patient gave a sudden lunge. My assistant, in determining the bladder capacity, noted that it was very large, about 1,000 c.c. He then allowed the fluid to return and in all about 600 c.c. returned. The man was asked to strain, and a small amount of fluid feces came back. The assistant suggested that he had gone through into the rectum, and to make sure he put his finger into the rectum and felt the back of the cystoscope. I pleaded with the man to undergo an operation but he refused. I notified the resident to call me up as soon as the man came in. Next afternoon the resident called me up, saying the man was feeling fine and was passing perfectly clear urine. I kept the man in bed and perfectly quiet for two weeks, and from that time to this he has passed perfectly clear urine and has never had any trouble from his accident.

Dr. D. N. Eisendrath, Chicago: I have had quite a large experience with both extraperitoneal and intraperitoneal rupture of the bladder, and I believe that if I had followed Dr. Fuller's suggestion my mortality probably would have been about 75 per cent. instead of about 10 per cent. in twelve cases. The only objection I have to Dr. Fuller's method of drainage is that it is altogether too radical for a man who has had as severe an injury as a recent fracture of the pelvis or a recent extraperitoneal rupture of the bladder. Every one of the cases I have had has been diagnosed within the first seventy-two hours, and it sufficed in all those cases simply to drain the bladder through a tube suprapubically, without any attempt to repair the rent in the bladder, and to drain the extravesical space through suprapubic drainage. With regard to the diagnosis, the chief point that I have always impressed on house surgeons is that if a man has met with any injury involving the region of the pelvis, the first thing the surgeon should do is to catheterize that patient if he can; if he cannot catheterize him, not to use any force at all, but to percuss above the pubes and if there is any dulness there to send word to someone at once who is more skilled in catheterization than he. If both then find that they cannot catheterize the patient, this means a rupture near the trigon, usually at about the junction of either the fixed portion of the urethra or at the anterior portion where it is attached to the symphysis pubis. If that is the case, the best way to do is not to try to do an external urethrotomy, but to do a retrograde catheterization, no matter whether the rupture is of the extraperitoneal portion of the bladder or of the deep urethra. It is better not to waste time, but to go in from above, and if one finds a rupture of the urethra one can retrograde catheterize the patient much more quickly. If one has an extraperitoneal rupture of the bladder the bladder can thus be drained.

Dr. Eugene Fuller, New York: Dr. Eisendrath seems to be doing with his patients exactly what in my paper I said was generally done with them, that is, they are discharged from the hospital crippled, of no earthly use; not dead, but they might as well be. If you get a pus pocket outside of the bladder in which material has extravasated how is a patient going to get well by catheterizing or by fussing with him? He does not get well. This radical operation of mine is not horrible because you do not as a rule have to tie a blood-vessel in its performance and it is of slight danger. I have done this supposedly horrible dissection over six hundred times with but one death and that person died because he had granular kidneys. An operation that is terrible ought to have a bad record, and this one has not. It is technical. There is no use jumping on it because it is technical, and trying to sidetrack it on that account. It is far better to take a cadaver, do a little dissecting, thus mastering the technic and then to try the operation. The whole thing is to get these patients well. These cases belong to a neglected branch of surgery, and the old way of doing nothing with them except seeing that they have a pervious urethra and leaving them alone does not cure them. The cases I reported were in a lot of derelicts who had been the rounds. The patients had been in four or five hospitals when I took hold of them, and I cured them. Dr. Pilcher wanted to know if I so treated these patients at the time of the injury. These are the cases in which the injury had taken place a long time before and in which extravasation is seen. If one gets a man with a rupture of the bladder immediately after the injury one naturally then would open suprapubically and drain as I stated in my paper. Then one probably would get ahead of the extravasation and prevent its occurrence.

THE MECHANICS OF A PLASTER-OF-PARIS CAST IN FIXED LATERAL CURVATURE OF THE SPINE *

E. G. ABBOTT, M.D.
PORTLAND, ME.

It is absolutely necessary to know the exact position of the anatomic parts entering into a deformity in order to correct it.

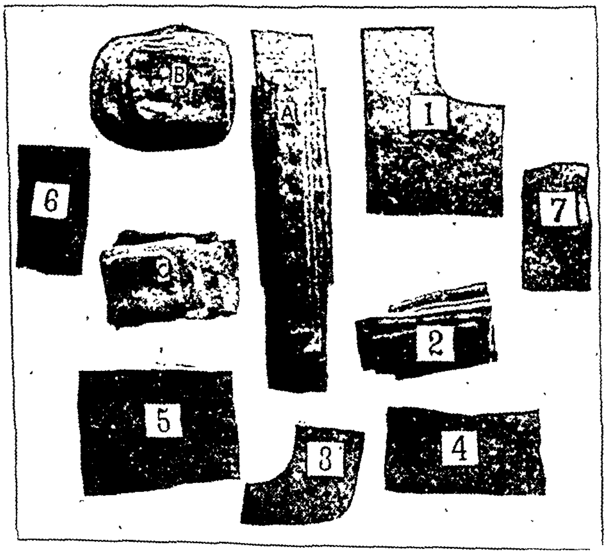

Fig. 1.—Pads used in the treatment of scoliosis.

Overcorrection or the reversal of the deformity is necessary to effect a cure. Overcorrection is obtained by pushing the parts back through the same arc which they passed when the deformity developed, and thence through a similar arc to a position exactly opposite to that of the original.

In order to know through what arc the parts travel in the development of a deformity, they must be traced from their normal positions to that of the deformed.

Scoliosis is developed from a normal physiologic position and becomes pathologic only when the individual is unable to reverse this position at will. Scoliosis in its beginning and through its development to a certain stage is a position of flexion, plus lateral bending plus rotation of the bodies of the vertebrae toward the convexity of the lateral bend.

It is first a normal physiologic position assumed at will, becomes pathologic after habitual assumption and may be easily created in the normal spine.

With a knowledge of the position of the parts in a normal spine, the position of the parts in a scoliotic spine and the arc through which they have traveled in the development of the deformity, it is possible to overcorrect or reverse the deformity, if it is borne in mind that these parts must pass back over the same route which they traversed to a normal position and thence through a similar arc to a position opposite to that of the original. Now the position must not only be understood in a general way, but an exact knowledge of every case must be obtained in order to apply intelligently the necessary force to reduce the deformity. Without this exact knowledge of the position of the parts in scoliosis, the force may be applied so that the deformity is increased rather than lessened.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

The spine must be flexed, pressure made laterally against the curve and against the rotation, and if this is done with precision the spine must go into the overcorrected position, unless it is too firmly fixed in its deformity.

The principle is the same in all cases, but its application differs. Let us note at this point what, in a general way, is the position of overcorrection, before proceeding to analyze just how this may be obtained. Using the familiar figure of a boy sitting in an improper attitude at a desk writing, it may be seen that the position is that of flexion, plus lateral bending, plus rotation of the bodies of the vertebrae toward the convexity of the lateral curve, and there may be one or two curves according to the position of the pelvis.

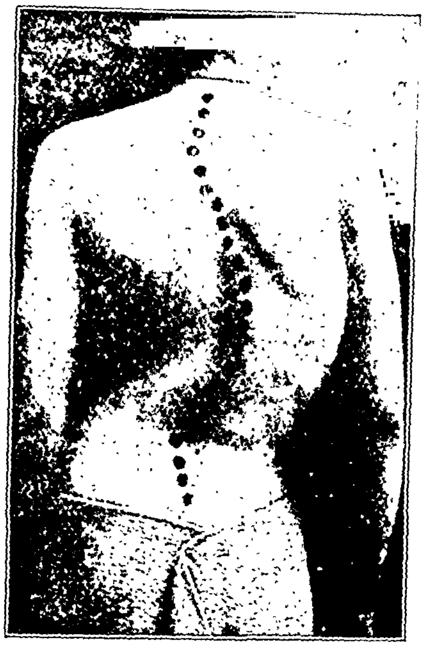

Fig. 2.—Patient with scoliosis.

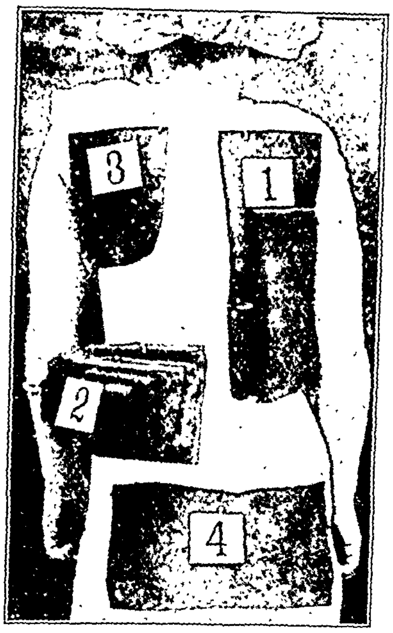

Fig. 3.—Showing method of application of posterior pads.

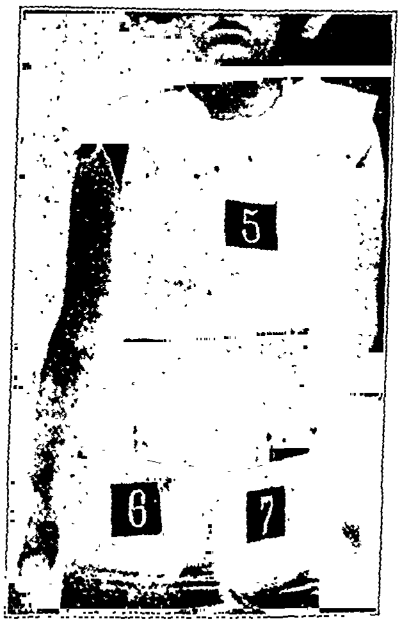

Fig. 4.—Application of anterior pads.

Now, in order to reverse this position we simply turn the child to the other side and the parts reverse their position, but the flexion remains unchanged. This is the position of scoliosis, be it physiologic or pathologic, and all other changes are secondary.

After the patient is placed in the position of flexion and the straps applied to pull the parts toward the position of overcorrection, the corset must be so shaped that the pressure against the fixed points continues to force the parts into an overcorrection. It is scarcely necessary to state that various forms of apparatus for pulling the patient into position might be used, but the exact position into which the patient must be forced must be borne in mind, and it is the application of a corset which will allow of reduction of the deformity that seems to present some difficulties. The corset must be heavily padded with saddler's felt, cut in suitable pieces according to the size of the patient. The technic may, perhaps, best be described by diagrams and illustrations showing just where force is applied, the fixed points in the corset and the necessary pads both permanent and removable used in the corset. Figure 1 represents all that are usually required, and the permanent ones, or those left in the corset, against which pressure is borne, are numbered and those used to shape the corset are lettered.

The positions which they occupy may be shown by placing them on a patient with scoliosis (Fig. 2). The permanent pads are placed posteriorly as shown in Figure 3, and anteriorly as in Figure 4. The posterior ones are fixed points in the corset. Pad 1 is composed of two pieces of felt placed over the bulging ribs, and so cut that it covers the shoulder blade and passes beneath the axilla. Pad 2 is placed in the lumbar region. It consists of several layers of felt so that firm pressure may be made against the left lumbar curve. Pad 3 is placed under the axilla and over the left shoulder. Pad 4 is placed across the sacrum. These four pads, 1, 2, 3 and 4, are points against which pressure is made and are never changed.

On the anterior surface of the body there are three pads, all permanent. Pad 5 passes across the thorax and Pads 6 and 7 are placed over the anterior superior spinous processes (Fig. 4). The removable pads are placed as in Figure 5. The long pad marked A is about 4 inches in thickness at the center and tapers at the ends. It is for the purpose of allowing more flexion. Pad B is placed over the concave ribs, and shapes the corset so that rotation may be overcorrected in the dorsal region. Pad C is placed in the lumbar region and allows the lumbar spine to overcorrect.

Three undervests, or coverings, are placed on the body. The permanent pads are put between the first and second cover and the removable pads between the second and third. The covers hold the pads in correct position, and also allow of easy removal of those to be taken out after the corset is finished.

Figure 6 illustrates the necessary straps to pull the patient into the proper position in a case such as shown in Figure 1. Strap 1 passes around the axilla, making lateral traction on the upper end of the dorsal curve. Strap 2 encircles the thorax, making traction on the ribs which join the vertebrae at the apex of the dorsal curve. Strap 3 makes lateral traction on the lumbar curve at its apex. Strap 4 passes around the pelvis and pulls against the lower end of the lumbar curve. Strap 5 is a rotator which is attached to Strap 2, and passes across the thorax and directly back. Strap 6 is attached to Strap 1 and pulls the low shoulder forward and upward. Strap 7 passes over the high shoulder and pulls it backward. Strap 8 is attached to Strap 3 and is a rotator which pulls against the thick pad of felt marked 2. Strap 9 tilts the pelvis. With the pads placed on the patient as indicated in Figures 3, 4 and 5, and the straps applied as in Figure 6, traction is made on them and the body is pulled in the direction of overcorrection. The plaster corset is then applied. As soon as the plaster hardens, windows are cut as in Figures 7 and 8. The window or slit in Figure 7 is for the purpose of inserting felt pads to induce further flexion. The windows in Figure 8 are over the removable pads B and C, and allow the depressed ribs and lumbar region to be pressed backward. At Point 1 (Fig. 8) the spine is 4 inches in front of the cast, that is, the spine may be further flexed 4 inches before it comes in contact with the plaster. Points 2 and 3, same figure, are fixed points which cannot change. When felt is inserted over the thorax through the slit or window (Fig. 7), the spine flexes further, carrying with it all of the body except those parts under Points 2 and 3, Figure 8, and if the deformity is not too extreme, it is possible to obtain overcorrection by inserting enough pads over the thorax to force the spine against the corset at Point 1 (Fig. 8). Should the lateral curves still remain, the corset is cut away along the dotted lines under the axilla and hip, and pads are inserted at 4 and 5.

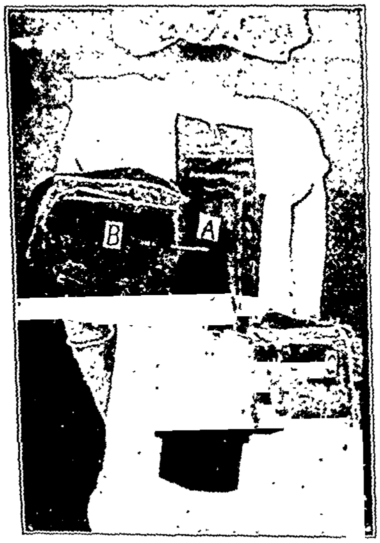

Fig. 5.—Showing position of removable pads.

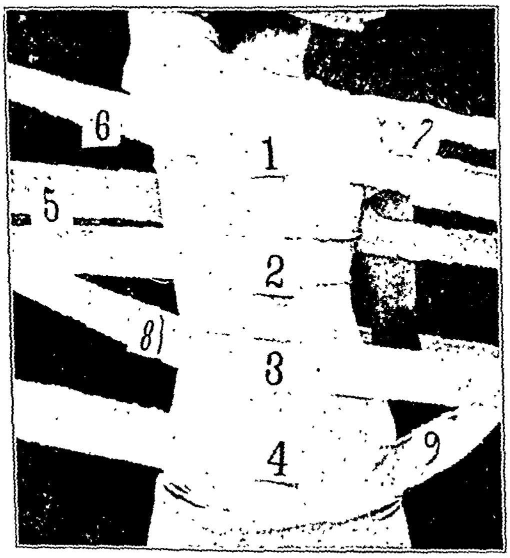

Fig. 6.—Straps used for pulling patient into position.

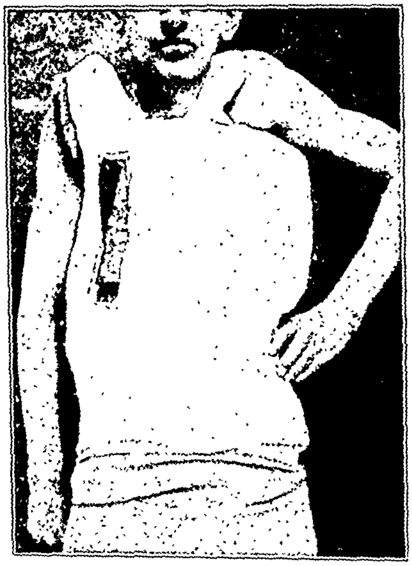

Fig. 7.—Showing window or slit for inserting felt pads to induce further flexion.

Care must be exercised that the traction is applied at the exact point needed. For example, if force is used against points which are apparently opposite the part of the curve against which pressure is needed, the deformity is made worse. It must be borne in mind that the ribs run downward as well as outward, and pressure should be made at proper levels.

As already stated, the position into which the patient must be placed in order to overcorrect must be thoroughly understood in every case, and the force must be applied with precision. Unless such precaution is taken, more harm than good may be done.

ABSTRACT OF DISCUSSION

Dr. Paul A. McIlhenny, New Orleans: I have not been able to get results, except in those cases in which we have what Dr. Abbott terms a "total scoliosis," or one in which there is only a slight curve in the lumbar region. I have followed, as closely as I could, instructions given in the various publications that I had access to; and I have obtained results in the moderate form of dorsal curve. In the marked cases of structural scoliosis, however, with a marked compensatory curve in the lumbar region, I have found an insurmountable obstacle, so far as I was concerned. Perhaps I am at fault. Other men have obtained these results in the double curves, as Dr. Abbott has, but I have not. There is some point in his technic, I believe, that I have missed; and I should like to get some light on why I cannot get a reduction of that compensatory curve or a correction of the primary curve, when I can get it in what we may term "total scoliosis" of the structural type.

Dr. Roland Meisenbach, Buffalo, N. Y.: Now that we are getting the results in the average type of structural lateral curvature of the spine, it will be necessary for us to consider more at length what can and what cannot be done for the severer types, which are so very common and which certainly require attention. In view of the recent progress in the treatment of scoliosis and the gratifying results obtained by Abbott's method in the average type of fixed lateral curvature, we should not give up the severe types in despair, but should attempt to do something for them. We must realize that the spine is not the only essential part of the patient, but that cardiac pressure, lack of excursion of the ribs, nerve pressure and visceral disturbances should be thought of. In the compound curves, the condition is even more exaggerated, and if carefully followed, much good can be done the patient, not only so far as the general symptomatology is concerned, but also in the actual anatomic straightening of the spine. The questions arise: How far shall we correct, and how much traction shall we apply, and what is the patient's endurance for correction? The last can only be determined by a thorough examination by internists, bacteriologists and pathologists, and by the orthopedist. I have had this emphasized many times, and I seldom undertake a case of a severe type unless I have had complete records of the patient made by a number of men. In the average and severe types more correction can be obtained, with less danger to the patient, if this method is followed carefully by the orthopedist. Not only can more correction of the spine be obtained, but such symptoms as muscular twitching and indigestion will rapidly disappear. I further believe that the cases should be taken early, and also in the severe types should be vigorously treated and not be allowed to become utterly helpless, even though the spine is not replaced in a perfectly straight line.

Dr. **Henry W. Frauenthal**, New York: I have used the Abbott method in a great many cases and from my experience I think that most men expect to get results too quickly. That is what I tried to do in the beginning, and I found that I was exerting too much pressure. This accounts for the fact that Dr. Abbott has increased the thickness of his pads to 2 or 3 inches. I think that if we have more patience and do not expect a perfect result in too short a time, and if we manipulate the backs very much as we do club feet that we try to correct without cutting, some of these bad backs will make a remarkable recovery. I have treated about a hundred and have got much better results than by any other previous method.

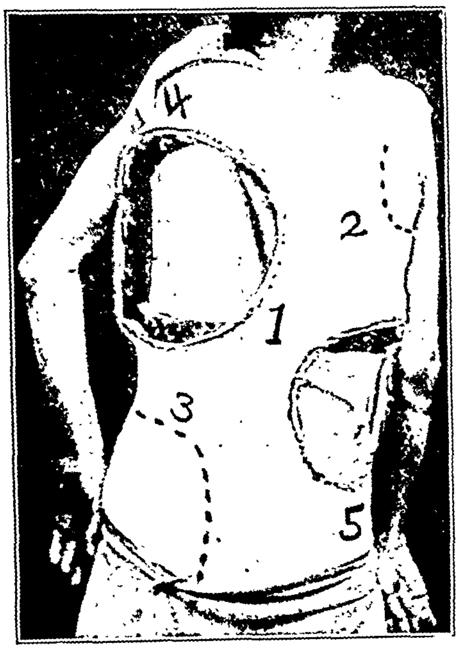

Fig. 8.—Showing windows for the insertion of pads.

Dr. **H. Winnett Orr**, Lincoln, Neb.: Having had the privilege of acquiring this method directly from Dr. Abbott, two years ago, I have treated more than fifty patients since then by the Abbott method. One thing that I have learned from my experience in these cases is that it is more important to begin an Abbott treatment with a thorough comprehension of Dr. Abbott's principles of pathology and treatment than it is to endeavor to use exactly the same technic as he employs. Dr. Abbott has himself obtained better results with the method up to the present time than has anyone else who has tried to follow him. I venture to say that by mastering the principles of the method and then working out a technic suitable to one's own hands and fingers, the treatment of these patients will give much more satisfactory results than can be obtained in any other way. I have refused no case of this kind since Dr. Abbott showed me how to treat them, not because I felt that I could cure all, but because I found even the worst susceptible of some improvement. I treated over again six or eight patients in whom I had formerly failed to gain improvement by other methods. All these patients are loyal and enthusiastic about the Abbott method.

Dr. **Charles A. Parker**, Chicago: My experience is not so great as that of some others, yet I have handled quite a number of cases. One sees quite a number of them in Chicago. In the severe types of cases that one most wants to help I have seen improvement, but no cure. I do not want to say this to discourage; it is quite probable that Dr. Abbott has cured many of these patients, but the bad cases, in my experience, do not recover. There are several reasons for that I think. We have been showing the congenital deformities in scoliosis. Scoliosis high up in the neck takes in the upper dorsal region. The inherent conditions constitute another reason in the twisted vertebrae and transverse processes on the convex side. When lateral pressure is made on the ribs of the convex side with the leverage behind the center of the bodies, the tendency is to increase the rotation or flatten the angle of the ribs. The angle of the ribs has been increased in many cases, although the affected portion of the spine may be moved nearer the middle line.

Dr. **James K. Young**, Philadelphia: Dr. Abbott has a great advantage over other men practicing this branch of the profession because he can keep his patients in his hospital as long as he desires. So long a time is required for a cure that much difficulty is experienced in this respect. I have seen him treat patients in his own hospital and I have much confidence in his method. The mild functional forms of scoliosis do not require forcible correction, as they can be treated best by gymnastics and postural methods which I have been successfully using for over twenty years. I was glad to hear Dr. Abbott say at the meeting of the American Orthopedic Association in Philadelphia, that he took more time to treat severe cases, as this coincides with my experience in using his method. Certain forms of scoliosis are not suitable for this form of treatment, as severe paralytic deformity, supernumerary bones, empyema, rickets and softening of the bones of unknown etiology. Severe cases must be treated by a forcible method and in selected cases there is none so good as that of Dr. Abbott.

THE THREE CARDINAL CLINICAL SIGNS OF FRACTURE INTO OR NEAR JOINTS *

WALTER G. STERN, M.D.
Orthopedic Surgeon to the East Side Free Dispensary and to the Mount Sinai Hospital
CLEVELAND

The vast majority of fractures seen by the orthopedic surgeon are fractures into or near a joint, and of these too large a proportion are overlooked by the surgeon or practitioner rendering aid and are diagnosed as "sprains" or contusions. Roentgenologists affirm that at least 90 per cent. of all sprains coming to them for roentgenoscopy are really fractures of some sort and not sprains.

Be this as it may, few fractures about joints present all the usual classical symptoms of fracture, namely, crepitus, preternatural mobility or elasticity (Albert), deformity, angulation, shortening, loss of function, etc., either on account of an impaction of the fragments, incomplete fracturing or because one fragment may be too small and too firmly attached to the structures of the neighboring joint or the parts too tender to permit of the necessary motion between the fragments for the elicitation of the foregoing symptoms.

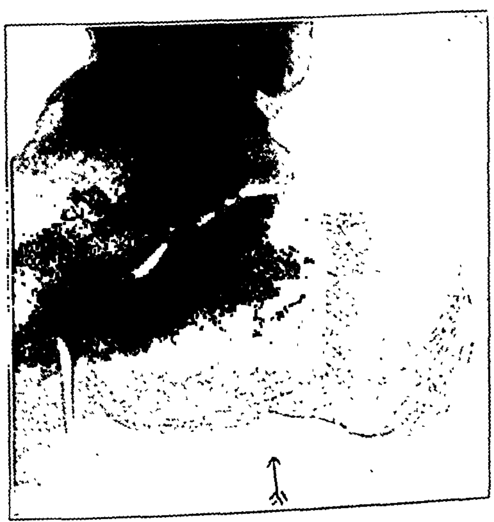

Fig. 1.—Avulsion fracture of os calcis (Case 1). Patient made a sudden jump to avoid being run over by an automobile. Diagnosed as "sprain" despite the pain, tenderness, swelling and ecchymosis which appeared a few hours after injury.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

While the general surgeons, through whose teaching the practitioners have learned to depend solely on the presence of crepitus, preternatural mobility and loss of function for their ability to make a diagnosis of fracture, are lamely offering such terms as "juxta-epiphyseal sprain" and "sprain-fracture" as stop-gap compromises; and while, for instance, Rose and Stewart state that "the ligament (at the lower end of the radius) is stronger than the bone and in the majority of cases on the cadaver pulls out the bone surface or causes by its stress a 'sprain-fracture' across the impact-receiving area," Helfreich, than whom no one has made better cadaver experiments on this subject, knows nothing of these hybrids and shows such cases to be incomplete, bending, arrachment, compression, fissure or torsion *fractures.*

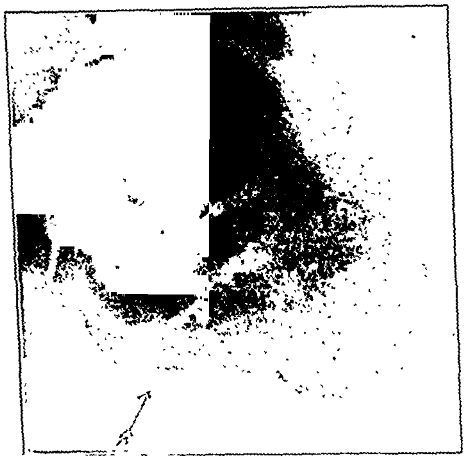

Fig. 2.—Fractures of os calcis (Case 2). Patient walked for two weeks; came to office unaided except by adhesive plaster strapping; foot much swollen and badly discolored when roentgenogram was taken. Pencil tenderness marked.

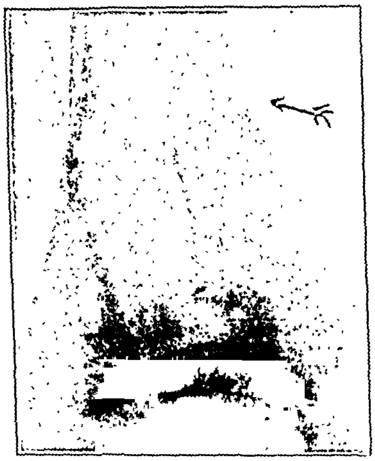

Fig. 3.—A "sprained" ankle now the basis of a malpractice suit (Case 3).

On the basis of a considerable experience with such atypical fractures, confirmed as such by the use of the Roentgen ray, I offer the following triad of symptoms, which I have always found present in the traumatic fractures of healthy bones as sufficient for a diagnosis, even when present alone, without any or all of the usual classical signs:

1. Localized bone tenderness over the fracture point or "pencil" tenderness.
2. Swelling, beginning at and spreading from seat of fracture.
3. Bloody discoloration or ecchymosis, spreading from this vicinity.

The fracturing of healthy bone gives rise to a greater or lesser degree of spontaneous pain, which, however, the fortitude of the patient may completely hide. While the entire member is usually sore to the touch, firm pressure about the seat of fracture will reveal a definite, constant point or line of great bone tenderness over the fracture. Often the tenderness is so exquisite that the patient can bear but the slightest touch to the fractured part of the bone, while pressure elsewhere is noticeably much less painful. It has not been unusual to find fractures so insensitive as to cause little loss of function, exhibiting the same marked bone tenderness. Palpation or pressure with the rubber tip of an ordinary lead-pencil so simplifies the mapping of this symptom that I have chosen the term "pencil tenderness" to describe it. This symptom persists for days and even weeks; in one case of undiagnosed and untreated fracture of the lower end of the radius, it was easily elicited as late as four weeks after the accident. While too much diagnostic importance should not be given to the presence of the bone tenderness alone, in the absence of signs of inflammation it is extremely suggestive of fracture and calls for the use of the Roentgen ray.

The characteristic swelling of fracture appears at once and is at first colorless. It arises and spreads from the injured area. It is doughy yet firm, hard but not inelastic, and is quite unlike the swelling of an inflammatory process.

The ecchymosis is dependent on bone hemorrhage for its production and does not make its appearance for at least twenty-four hours after the injury, in contradistinction to the discoloration caused by the bruising of the skin and soft parts, from trauma. The other structures in the neighborhood of a joint, namely, ligaments, capsule, tendons, bursae, etc., do not possess such a free blood-supply that their injury or rupture should cause this characteristic extravasation of blood. Ecchymosis is said never to occur in the fracture of the bones of the finger. I am positive that I have seen it in the few early cases coming under my observation. The diagnosis of finger fractures, however, should give little or no trouble.

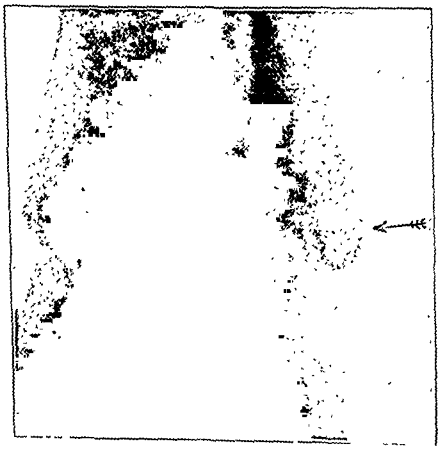

Fig. 4.—Type of injury often diagnosed as sprained ankle (Case 4). Patient twisted ankle getting off of car. No crepitus, etc.

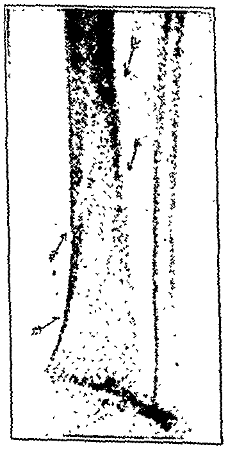

Fig. 5.—Spiral fractures of tibia (Case 5); no crepitus, deformity, etc.; the only symptoms were pain, "pencil tenderness," swelling and discoloration.

Roentgenograms, taken stereoscopically or at right angles to each other, should always be made to confirm this symptom complex. Even if the plates are good ones, negative roentgenographic findings should not be held to be final *if the clinical symptoms persist,* but another series of plates should be taken from ten to fourteen days later.[1] In preferring to trust the persistence of this symptom complex rather than the roentgenographic plates as ordinarily taken, I have in several cases been able to make the correct diagnosis of fracture and have it confirmed later on by other roentgenographic findings. The aspiration of the joint fluid has at times changed the roentgenographic verdict from negative or doubtful to positive.

---

[1] Compare An Interesting Decision of a Law-Court on a Wrong Diagnosis, Vienna Letter, The Journal A. M. A., May 2, 1914, p. 1416. In this case the early roentgenograms showed no fracture; the patient, however, evidently presented the symptom complex herein described, yet he soon walked on his injured foot. Roentgenograms taken some time later clearly showed a fracture of both the tibia and fibula.

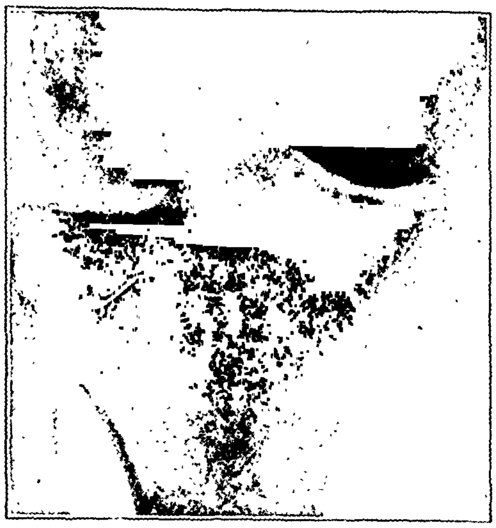

Fig. 6.—Undiagnosed fracture of head of tibia (Case 7).

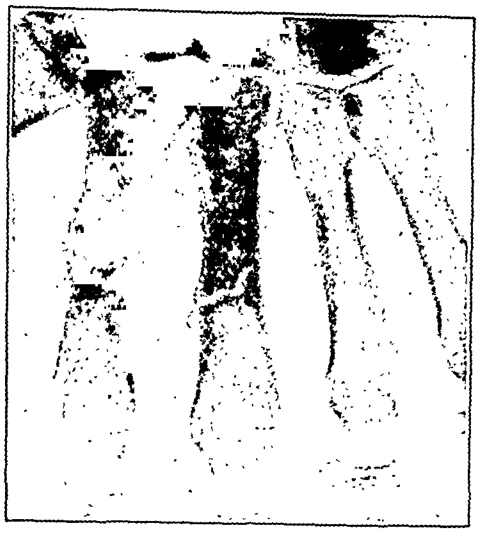

Fig. 7.—Undiagnosed and untreated fracture in hand (Case 9) from baseball.

I have seen fractures of every joint of the body, excepting the vertebral column, in which all the usual classical signs have been absent, which have been correctly diagnosed on the strength of this clinical triad. The following examples will suffice:

Case 1 (Fig. 1).—While jumping out of the way of an automobile the patient felt something give way in the heel. Has some pain, but can walk with a limp: diagnosed as sprained ankle. No crepitus, preternatural mobility, etc. Pencil tenderness, swelling and ecchymosis present six days after injury.

Case 2 (Fig. 2).—Patient had foot caught in an elevator; taken home in buggy; limped from buggy to house; seen soon afterward by a physician. Line of bruise was present in skin; pain and swelling present, but there was no crepitus or preternatural mobility. The following day he walked, with the aid of a cane, one-half mile to the street-car, then one-fourth mile to the company surgeon's office, where he had ankle strapped under diagnosis of contusion and returned the same way he came. Roentgenogram is said to have been doubtful. Clinical triad present at end of second week.

Case 3 (Fig. 3).—Patient fell from scaffold and was taken to hospital. No crepitus or other common signs of fracture. Diagnosed and treated for sprain. Presents pencil tenderness, swelling and ecchymosis.

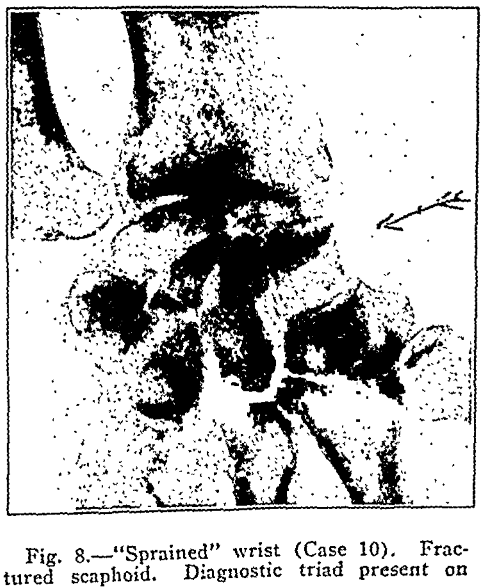

Fig. 8.—"Sprained" wrist (Case 10). Fractured scaphoid. Diagnostic triad present on fourth day.

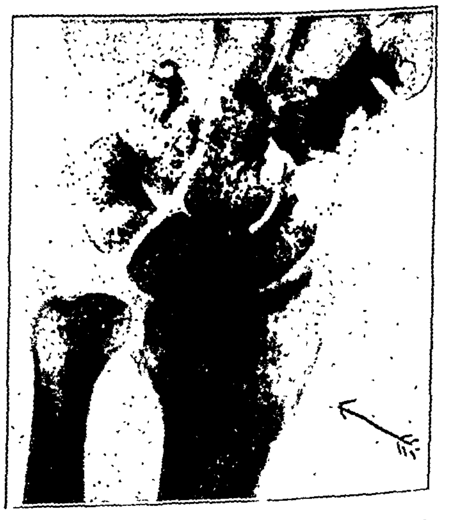

Fig. 9.—"Sprained" wrist from backfire of engine (Case 11). Patient steered large automobile many miles after injury occurred.

Case 4 (Fig. 4).—Patient fell from street-car and twisted ankle; can walk with a limp and works daily as a seamstress. There is much swelling, extreme bone tenderness and some discoloration. Case diagnosed by attending physician as a sprain.

Case 5 (Fig. 5).—Spiral fracture of tibia, all classical signs of fracture absent. Exquisite pencil tenderness, marked swelling, slight ecchymosis present.

Case 6.—Patient kicked by a horse. No crepitus, shortening, loss of function, etc. Patient can limp on this leg. Marked pencil tenderness two weeks after injury. Attending physician could not elicit crepitus immediately after injury, and on account of swelling diagnosed periostitis.

Case 7 (Fig. 6).—"Barked shin" in fall from a low buggy. Patient walks with aid of single crutch. No crepitus, preternatural mobility, shortening, etc. There is a tense tumor above and to inside of patella. Motion of knee-joint almost free. Line of tenderness over head of tibia, with swelling and discoloration. Puncture of knee-joint evacuated bloody fluid containing fat globules. Roentgenogram after puncture clearly positive of fracture.

Case 8.—Fracture at surgical neck of humerus; both attending physician and insurance examiner hold case to be rupture of the biceps tendon on account of the absence of all classical signs of fracture.

Case 9 (Fig. 7).—Patient hit by pitched ball; has been able to use hand freely but with some pain; fracture was never suspected. After two weeks clinical triad presented the only symptoms of fracture readily demonstrable.

Case 10 (Fig. 8).—Fractured scaphoid of wrist. Point tenderness, swelling, ecchymosis and immobility of joint are the only symptoms of fracture present.

Case 11 (Fig. 9).—Automobile fracture from backfire. Patient drove automobile several miles to see surgeon, who found none of the ordinary symptoms of fracture present and called condition a "sprained" wrist. Clinical triad present on the third day.

Case 12 (Fig. 10).—Fracture of lower end of humerus, diagnosed as sprain. Patient has limited motion in elbow-joint together with clinical triad. Ordinary attempts to elicit crepitus and preternatural motion unsuccessful.

Case 13 (Fig. 11).—Impacted fracture of humerus diagnosed as "torn ligaments." Shoulder motion quite free. Arm very painful; no shortening, deformity or crepitus. Swelling and bloody discoloration marked to the elbow-joint, which is held very stiff.

Case 14.—Patient was thrown from a swiftly moving car, striking pile of stone with hip. Fluoroscopic examination at a hospital is said to have shown a fracture of the femur just above knee. Patient asserts that knee was less painful than hip "bruise." Had no bloody discoloration about knee, but thigh was discolored and tender for many weeks. Discharged from hospital with plaster cast to knee. Has complained of soreness in the hip for the past two years. Careful roentgenographic examination now shows that there never had been a fracture in the neighborhood of the knee, but there existed an easily diagnosed thickening and fracture of the greater trochanter.

COMMENT

Granted that crepitus is not essential in making the diagnosis of fracture, violent attempts to elicit same are unjustifiable as well as brutal.

An anesthetic is as unnecessary in making the diagnosis of fracture as it is in arriving at a diagnosis in hip disease.

Every suspected fracture should be roentgenographed.

Cases which will show crepitus and preternatural mobility under an anesthetic will show preternatural elasticity without one (Albert).

Ninety per cent. of all sprains coming for roentgenography or consultation are fractures.

When all the usual classical signs of fracture are lacking, the presence of localized bone tenderness, swelling and bloody discoloration alone is diagnostic of fracture.

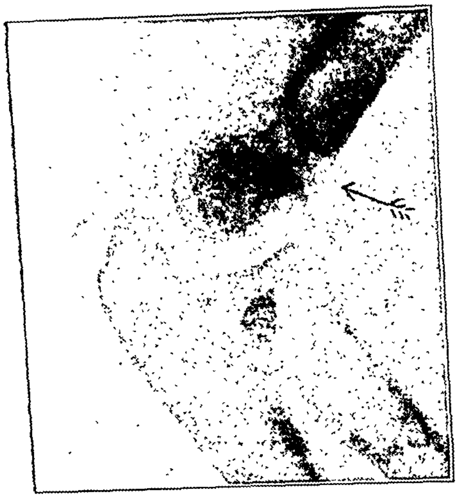

Fig. 10.—"Strained" elbow (Case 12).

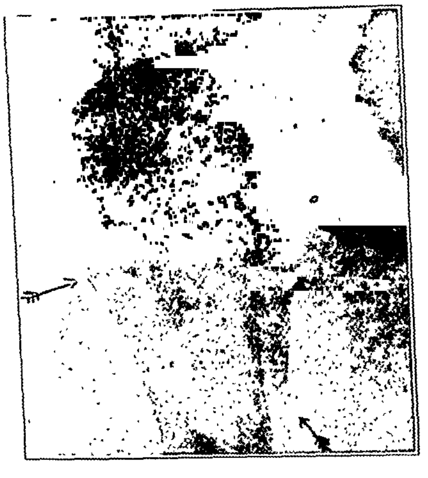

Fig. 11.—Fractured humerus diagnosed as torn ligaments and "sprain" (Case 13). Diagnostic clinical triad marked.

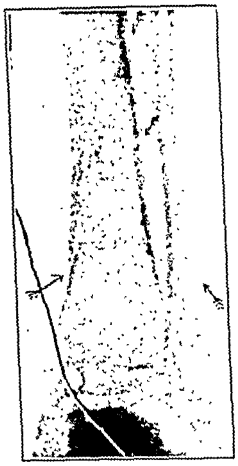

Fig. 12. — Undiagnosed spiral fractures of tibia and fibula. Patient walked into East Side Free Dispensary unaided, two days after injury.

The old adage "a sprain is worse than a break" is based on faulty diagnosis and subsequent lack of proper treatment.

ABSTRACT OF DISCUSSION

Dr. F. J. Cotton, Boston: This paper brings out an interesting point relative to the diagnosis in these old cases. A great many cases are overlooked, because we have subconsciously expected to find the ordinary classical signs of fracture. I am going to suggest another phrasing and that is: If there are local signs of injury where there is no reason to think the force of impact took place, it means fracture. This is phrasing backward what Dr. Stern said about the local signs.

If a man falls in a sitting position, and subsequently develops tenderness in the back, it is probable that that man has a broken back. He did not hit his back when he fell, but something in his back gave way. I think that these cases may be more safely tested by that rule than by any other if it is added that it is particularly true in cases in which there are no signs of local impact. One can get the localized tenderness and ecchymosis over the bone, if a patient gets a blow, and can confirm the diagnosis by means of the Roentgen ray. Dr. Stern's paper calls attention to the fact that we are not dealing with sprains but with real fractures. We should have proper terminology for these obscure injuries around the joints.

Dr. Frank E. Peckham, Providence, R. I.: Dr. Stern said that the roentgenologists claim that of the cases presenting themselves for their observation as sprains, 90 per cent. were true fractures. You should not reason from that, however, that 90 per cent. of all sprains were fractures; because the patients presenting themselves to the roentgenologists have already had treatment and the condition has not been recognized. I should not think that 90 per cent. of all sprains—or rather, cases thought to be sprains—were fractures.

Dr. G. W. Stern, Cleveland: I do not think Dr. Cotton has quite made the distinction that I wish to convey between the immediate discoloration of the parts from the bruising of the skin in the cases of fracture from direct violence, and the ecchymosis due to bone hemorrhage which makes its appearance about twenty-four hours after the injury. It is this latter type of bloody discoloration which, with localized bone tenderness and swelling, make up my diagnostic triad. In cases due to indirect violence I believe Dr. Cotton's trite aphorism expresses my thought quite happily. There are certainly such injuries to the ligaments and other soft structures of a joint as are known as "sprains" or "strains;" but the laity and, indeed, most physicians are wont to call any painful injury in the neighborhood of a joint, outside of a most outspoken fracture, a sprain. With such cases my deductions—of 90 per cent. being fractures—do not deal. On the other hand, it is equally true that almost all of the cases that are seen by the roentgenographer or consulting surgeon in which the symptoms of "sprain" have persisted or are severe, are true fractures. This is not only my own observation but also that of the present president of the American Roentgen-Ray Society.

The Need of General Culture as a Condition of Progress. —In the realm of ideas there is no such thing as spontaneous generation. Those who seem the originators of great movements are those who have been brought under great influences. Apparent exceptions to this rule, like Shakespeare or Darwin or Lincoln, prove, on examination, excellent examples. There is little difficulty in tracing historically the continuity of human thought. It follows that we cannot hope for a generation of original thinkers unless we immerse our students in the stream of the world's thought. The most inventive mind must have material on which to react, and cannot strike out in a vacuum.—Walter Libby, *Science.*

PROPHYLACTIC VACCINATION AGAINST EPIDEMIC MENINGITIS

A SUPPLEMENTARY NOTE

J. H. BLACK, M.D.
DALLAS, TEXAS

In April, 1912, Dr. Abraham Sophian, then of the Research Laboratory of the New York Board of Health, and I conducted a series of experiments to determine, as well as laboratory methods will permit, the value of prophylactic vaccination against epidemic meningitis. Injections of meningococcic vaccine were made on ten medical students who volunteered for the work. The details of this work with the results obtained were reported in The Journal.[1]

Eleven months later I repeated these experiments to determine what, if any, immunity could be demonstrated after the lapse of this time. Eight of the original ten vaccinated students were accessible. The technic used in the complement-fixation studies was identical with that formerly reported. The results of this study were reported in The Journal.[2]

With the effort to make this work as nearly complete as possible, I undertook in May, 1914, twelve and twenty-four months from the second and first examinations, respectively, a repetition of the complement-fixation studies. Table 1 shows the results obtained. It will be seen that all but one of the seven students at hand gave decided fixation in a dilution of 1:20, this, two years after the date of vaccination.

TABLE 1.—COMPLEMENT-FIXATION

Case No.	Dilutions				Control
	10	20	30	50	
1	++	++	—	—	—
2	+++	++	—	—	—
3	++	++	—	—	—
4	++	+	—	—	—
8	+++	++	—	—	—
9	+	—	—	—	—
10	++	++	—	—	—
Pos. con.	+++	+++	+++	++	—
Neg. con.	—	—	—	—	—

TABLE 2.—COMPLEMENT-FIXATION

Case No.	1 Month	1 Year	2 Years
1	200	150	20
2	200	150	20
3	100	150	20
4	100	100	20
5	30	*	*
6	*	*	*
7	200	150	*
8	250	100	20
9	100	250	10
10	200	250	20

* Student not accessible.

Table 2 is a comparison of the fixation of each student at one month, one year, and two years, respectively, after vaccination. The figures in each column refer to the highest dilution at which fixation was obtained.

While it is recognized that experimental vaccination of healthy individuals in the absence of an epidemic and the detection of immune bodies in their blood is an indirect way of proving its efficacy, and that the method must finally be judged by its clinical application, we feel that we are justified in drawing the following conclusions from these studies:

1. Prophylactic vaccination produces a high degree of immunity in most cases, this immunity being demonstrable at the end of two years. It seems a justifiable conclusion that most persons prophylactically vaccinated may safely consider themselves immune for at least two years. Exceptions to this will, of course, be found.
2. Some individuals may show an actual increase in immune bodies at the end of one year over those demonstrable soon after vaccination.
3. Fixation occurred with the serum of the positive control who has recovered from meningitis, but this fixation did not reach as high dilutions as did that of some of those vaccinated.[2] This has previously been found also in some others recovered from the disease.
4. Experimental evidence warrants us in concluding that prophylactic vaccination is a measure of the greatest value in the control of epidemic meningitis.

TRICHOTILLOMANIA

Richard L. Sutton, M.D., Kansas City, Mo.

We are indebted to the French school of dermatology, and particularly to Besnier,[1] Hallopeau,[2] Henri Fournier[3] and Brocq,[4] for the recognition and classification of the peculiar family of neurodermatoses which is represented by trichotillomania and dermatothlasia.

Trichotillomania, the *"trichomanie"* of Besnier, is an affection which is characterized by an abnormal desire on the part of an otherwise apparently sane individual to extract forcibly one or more of his own hairs.[5] The impulse is seldom cyclic, but is as sudden as it is uncontrollable, and Raymond's designation of *"tic de l'epilation"* is not an inappropriate one. The scalp, the eye-brows and lashes, and the beard are the parts most frequently attacked.

Dermotothlasia is a somewhat similar morbid state in which the affected individual possesses an ungovernable desire to rub, scratch or irritate the skin on one or several parts of the body.

TRICHOTILLOMANIA

Recently I had an opportunity to study two typical examples of trichotillomania.

Case 1.—The first case occurred in a married woman of 27, an American by birth and a housekeeper by occupation, referred to me by Dr. Charles W. Gosney of Kansas City. The patient had always been of a nervous temperament, but her family history was negative insofar as nervous or cutaneous ailments were concerned. Two years prior to the time of consultation she first became aware of the fact that she had acquired the habit of frequently jerking hairs out of her eyebrows whenever she was worried or subjected to prolonged periods of excitement. Despite her efforts to combat the practice, the habit grew stronger instead of weaker. She had never suffered from pruritus or other irritation of the supraorbital regions, and could not account for the propensity to remove the hair from these particular localities. The attacks were confined principally to the inner extremities of the brows, where the hairs protruded forward and were easy to grasp. It did not appear to matter which hand was used in the process of extraction. As the patient described it, she would have a sudden, intense desire to pull out one of the hairs (normal individuals probably experience a somewhat analogous sensation at times regarding one of the stiff vibrissae of the nose), and a second later she would be gazing at the freshly extracted appendage with its partially adherent root sheath.

[3] Fournier, Henri: Jour. malad. cutan. et syph., April, 1898.

[4] Brocq: Traite Elementaire de Dermatologie Pratique, Paris, 1907, ii, 398; Jour. des pract., March 26, 1898.

[5] "La trichotillomanie consiste essentielment en une impulsion qui pousse les subjects a arracher des poils; ce besoin de pratiquer l'avulsion constitute une veritable manie, et nous l'avons observee sans qu'il y ait de prurit notable" (Brocq).

The patient was a muscular young woman, with brown hair and eyes. Her chin was firm and well set, and in her general appearance there was nothing suggestive of hysteria or other mental ill-balance. The skin of the face was smooth and unmarked, with but a slight trace of seborrhea. The lower lashes were normal, but the upper were sparse and straggling, and it is exceedingly probable that the patient had removed many of these also. The eye-brows were apparently much abbreviated, and set wide apart, a space of more than 11 cm. separating the inner extremities. At a few meters' distance the impression given an experienced observer was that of a bilateral alopecia areata of remarkable symmetry. On closer scrutiny, however, it was found that a broad, indistinct, bluish band projected inward for a considerable distance from the terminus of each brow. When these areas were examined with a magnifying glass they were found to be thickly studded with new hairs, many of which were just reaching the surface. The patient stated that as soon as a fresh shaft was of sufficient length to be grasped it was promptly extracted. The hairs in the outer portions of the brows were undisturbed, and the smooth, regular manner in which they were arranged, together with the apparently normal condition of the underlying skin, indicated that the patient's statement regarding the absence of pruritus was correct.

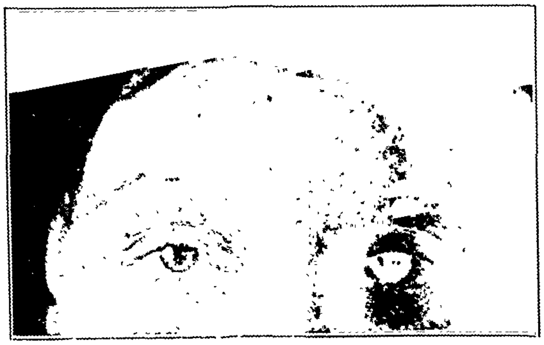

Fig. 1.—Trichotillomania, Case 1, showing absence of upper lashes and inner extremities of eyebrows.

Case 2.—The second patient was a schoolboy, aged 14, a native and resident of Kansas, who was referred to me by Dr. H. P. Ball of Kansas City. This patient has been under the care of Dr. B. M. Barnett of Rosedale, Kansas, for some time, and I am indebted to Dr. Barnett for the privilege of reporting it here. The neurologic history of the family is negative. There is one other child, a boy of 9. He is mentally and physically normal. The patient has always been of a high strung, nervous temperament. When a baby he sucked his fingers incessantly. Later, he chewed his nails. He has been a "mouth breather" nearly all his life. Although not very robust, he escaped the more serious of the diseases of childhood, and has never had a more serious disorder of the nervous system than the "habits" above mentioned. He has never suffered from headaches or eye strain, and there is no history of eczema or pruritus of the scalp.

On examination the patient was found to be a slender, fragile boy, with a shrunken chest and a retreating chin. The palate was arched and misshapen, and the teeth poorly aligned. The eye-brows and lashes were unaffected. The hair on the top and right side of the head was normal, but on the left side practically all of the stiff shafts were gone, and only the soft, fuzzy tips of the downy new growth were to be seen. The denuded skin was soft, smooth and pliable, with no trace of scratch marks.

The little patient stated that it was impossible for him to resist the impulse which occasionally prompted him to jerk out the stiffer hairs. The tendency was greatest whenever he became worried or excited.

TREATMENT

In the first case, rest and freedom from worry, with liquor potassii arsenitis in gradually increased doses, internally, appeared to benefit the patient's condition. The application of various anti-pruritics, such as phenol, menthol, camphor and tar, apparently had no effect whatever. Hallopeau has suggested the use of gutta percha and similar dressings of an impervious character in these cases. Probably a better plan would be to ameliorate the habit by keeping the hair shaved off for a period of several months. This patient absolutely refused to allow the adoption of this measure, but I hope to give it a trial later on. Dr. Barnett reports that the second patient has been considerably benefited by the use of tonics, principally arsenic.

If one excludes Brocq's *"acne excoriee des jeunes filles,"* as I think we should, true examples of dermatothlasia are exceedingly rare. Occasionally, however, one encounters a case of acaraphobia closely bordering on dermatothlasia. The following is an example:

DERMATOTHLASIA

Case 3.—M. P., female, spinster, physician, aged 52. This patient first consulted me in October, 1909, regarding a disorder which at first glance appeared to be a generalized pruritus. The disease had begun, three years before, with a slight itching of the skin on various parts of the body, and had continued at irregular intervals ever since. The integument was soft, moist and apparently normal, and there were no signs of senile atrophy. The urine contained considerable quantities of indican, but no albumin or sugar. The blood-pressure was not excessive. The hemoglobin was usually below 70 per cent. The cranial hair was short, dry and matted, and the scalp rough and scaly, probably a result of frequent and violent manipulation with the patient's nails. There were no signs of seborrhea or seborrheic dermatitis on the face or over the sternum. There was no hepatic tenderness, and the patient was not jaundiced. The woman's principal complaint was that she had "bugs" in her skin. She would suddenly pounce on some small area, most often located on the scalp or limbs, rub vigorously for a few moments, and then triumphantly announce that she had captured one or more insects, and that they were contained in the minute, tightly rolled, oat-grain-like mass of epithelial debris that she had detached. Innumerable negative examinations of the material made no impression whatever on her, but left her as firmly convinced as ever that her integument was inhabited by a new species of small but exceedingly industrious insect that would eventually prove her undoing. On subjects other than this ailment the patient's mind was unaffected. She suffered but little from pruritus, but explained that the sudden development of a slight sensation

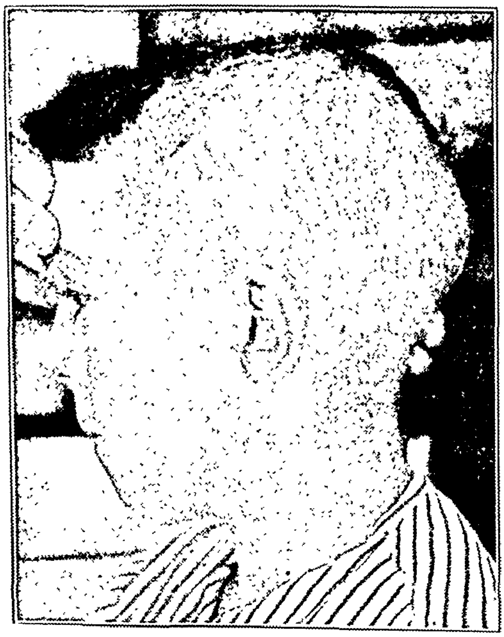

Fig. 2.—Trichotillomania, Case 2, showing extent of hair loss on left side of head.

of formication in the involved areas always precipitated the attack of rubbing. The forcible removal of a few of the outermost corneous layers invariably had a soothing effect on her mind, and after she had carefully burned the material and its supposedly dangerous contents, she was perfectly at ease, sometimes for hours. The patient was under observation for three years, and during that time almost every conceivable remedy was tried, always without relief. When last seen, the patient's condition was practically the same as at the time of the first consultation.

Lathrop Building.

DERMATOLYSIS

WITH REPORT OF TWO CASES

Wm. W. Cadbury, M.D., Canton, China

Recently I have come across two typical cases of the rare affection known as dermatolysis. The condition is defined in Stelwagon's Diseases of the Skin as a hypertrophy and looseness of the skin and subcutaneous connective tissue with a tendency to hang in folds, and has been spoken of as "loose skin," "cutis laxa," "cutis pendula" or "chalazodermia." It may be congenital or acquired. All parts of the skin share in the hypertrophy; it may be located in any part of the cutaneous surface of the body. There are no subjective symptoms and it is slowly progressive. The etiology is obscure though the disease sometimes begins at the site of an injury.

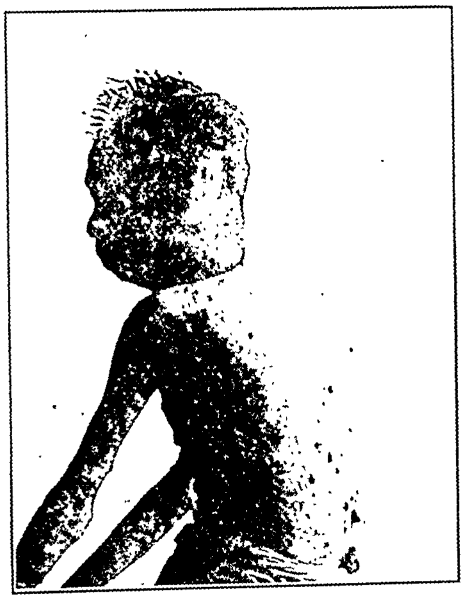

Fig. 1—Patient in Case 1. Note flap of skin and fibrous tumors on back.

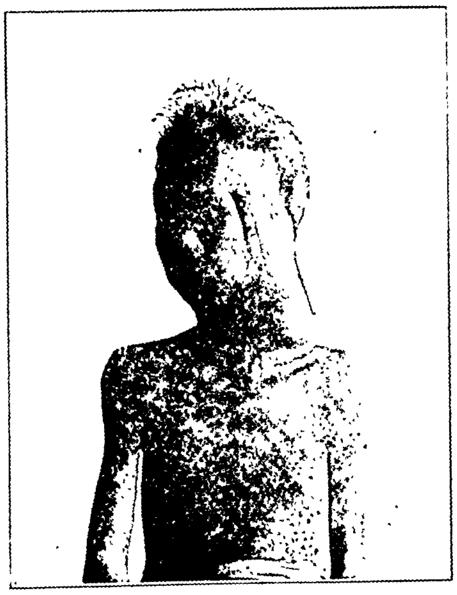

Fig. 2.—Front view of patient in Fig. 1.

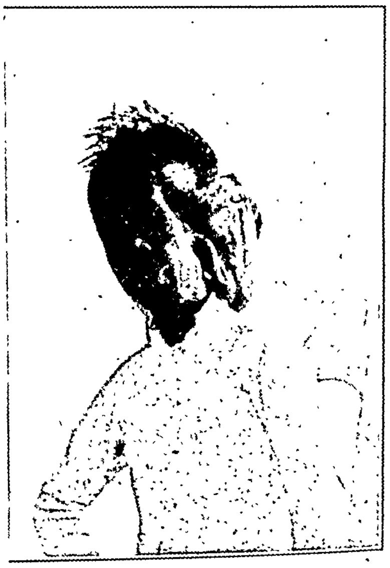

Fig. 3.—Flap of skin lifted to show ear.

The condition shows no tendency to decrease but rather to develop. Operative measures have been employed successfully when the hypertrophied flap of skin was troublesome.

It appears that fibromatosis is sometimes associated with dermatolysis, as in one of the cases cited below. In fact, the relationship of these two conditions seems to be not unusual.

Case 1.—P. S. O., a Chinese farmer, aged 33, was admitted to the hospital of the University Medical School, Canton, China, March 25, 1914, complaining of gastric distress, which was later diagnosed as gastric ulcer. Of rather slight build the patient presented a remarkable appearance on account of a large cutaneous flap hanging over the left side of his face. Over the back, chest and abdomen there were numerous fibrous tumors varying in size from that of a millet seed to a diameter of 1½ inches (Figs. 1, 2 and 3). The patient was below the average in intelligence and somewhat self-conscious of his peculiar appearance. He was discharged from the hospital April 7, in practically the same condition as on admittance.

Description of the cutaneous flap: This peculiar hypertrophic growth begins on the left side of the scalp at a point above the level of the eyebrows, falls down over the face entirely covering the left ear, which projects from the inner surface of the flap. It descends to the shoulder on which it rests. The flap measures 9 inches in length by 8 inches in width. The patient declares that at birth the flap was about 2 inches in length and has gradually been extending in size. In every way the skin resembles redundant scalp tissue. The external surface is studded with hair follicles from which recently clipped hairs project. The inner and external surfaces may be readily rubbed over each other. The color of the skin of the flap, like that of the rest of the body, is rather deeply pigmented. The loose skin may be readily raised up and the ear projecting from the inner surface disclosed (Fig. 3).

Case 2.—L. K., Chinese, aged 20, was admitted to the Canton Hospital in May, 1914, in order to care for a relative who was operated on for stone in the bladder. L. K. is not ill. When 5 years old he developed an abscess of the scalp behind and below the right ear and about 3 inches distant from it. The scar of this abscess is still visible. Ten years later he noted swelling of the scalp in this region. This has gradually increased so that at present the loose flap of skin extends 3 inches above the right ear, 2 inches below and is altogether 4 inches wide (Fig. 4). It is continuous with the tissues of the scalp, is slightly elastic and is not pendulous as in the former case. It is covered with hair. Patient feels no discomfort. The flap is said to be gradually increasing in size.

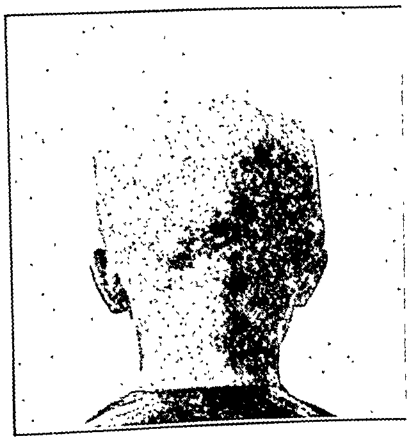

Fig. 4.—Patient in Case 2. Loose flap of skin behind right ear.

These two cases of dermatolysis, both of the scalp, represent the congenital and acquired form. In both cases the subject was below the average of intelligence. Neither was willing to have the redundant skin removed.

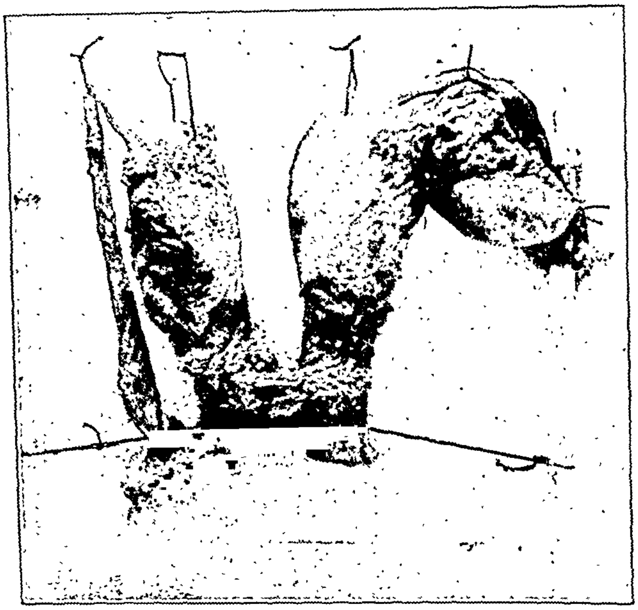
Canton Christian College.

Preventogram.—An hour's prevention may save a month of quarantine.—Pittsburgh *City's Health.*

A BICORNATE UTERUS WHICH CONTAINED THREE PREGNANCIES

Charles H. Parkes, M.D., Chicago

Mrs. H., aged 47, married twenty-five years; had three children and one miscarriage. At the first parturition forceps were used, and the perineum was extensively lacerated. Following the third childbirth prolapse of the uterus began, which increased slowly in degree, until, two years previous to operation, the cervix protruded from the vagina. On examination, a diagnosis of bicornate uterus was evident. The patient was a constant sufferer from the usual pains and from a profuse uterine discharge. Total hysterectomy was performed, followed by a complete recovery.



Bicornate uterus which contained three pregnancies.

25 East Washington Street.

THE THYROID GLAND IN PELLAGRA

Charles F. Beeson, M.D., Roswell, N. Mex.

Little attention has been given to the condition of the thyroid gland in pellagra. Some text-books do not mention it. According to Niles, in Lombardy, where there is much goiter and cretinism, physicians regard one disease as the cause of the other. He states that in the United States thyroid disease has not been noted in connection with pellagra to any extent. Out of 316 cases of pellagra investigated by a commission appointed by the Tennessee State Board of Health, this commission incidentally gave thyroid diseases as complicating in twenty-five instances, which was more than twice as many as any other complicating condition. The following case raises the question as to an etiologic relation between these two conditions:

The patient, a married woman of 45, presented herself April 13, 1913, and stated that she had always been in robust health until about one year previously. At this time she began having diarrhea with frequent passages accompanied often with colicky pains. This diarrhea has continued with more or less severity up to the present time. About five months ago she noticed that the back of both hands became rough, red and scaly, which she attributed to sunburn. She began having spells of aching, lost weight and became very nervous. She complained of dizziness and at times would walk like a drunken man. She also complained of indigestion accompanied by a sore mouth. A lump came into her throat and she said her neck-band became too tight. She said that her menstrual periods had been very irregular for several months.

Examination showed that the eyes were not noticeably prominent and von Graefe's sign was negative. The tongue protruded in the middle line, and was red and grooved transversely on the dorsum. It showed a bright red line along the under borders and was denuded of epithelium in spots. The tongue showed no tremor, nor was there any tremor of the fingers when extended. The sublingual glands were enlarged, and the ducts of Wharton were red and swollen. The thyroid gland was decidedly enlarged symmetrically. The backs of both hands were rough, scaly and dirty looking, with some redness along the knuckles. This eruption was exactly alike on both hands. Examination of the chest gave negative results. The abdomen was also negative except for some slight tenderness. Temperature, 98; pulse, 95; systolic blood-pressure, 120; hemoglobin, 90 per cent. The patellar reflexes were greatly exaggerated and there was slightly marked ataxia.

Patient was put to bed and fed liberally for about a month and was given iodin and arsenic. Her pulse dropped to normal in a few days and her nervousness gradually subsided. The eruption on her hands cleared up in about two weeks, only to flare up again in a few days, passing through a cycle of redness, roughness and desquamation lasting about three weeks. This eruption did not appear again. During this time the thyroid gland would apparently enlarge and recede. Her attacks of diarrhea gradually ceased and by fall all symptoms except some nervous exhaustion had disappeared. At the present time, Oct. 1, 1914, she is in good health and her thyroid is not noticeably enlarged.

What part did the thyroid play in this case? Was it a mild case of pellagra, simply complicated by an enlarged thyroid, or was the perverted action of the thyroid the cause of the pellagrous symptoms?

A TACK IN THE EPARTERIAL BRANCH OF THE RIGHT MAIN BRONCHUS

Wilhelm Lerche, M.D., St. Paul

A girl, aged 6 years, six days previous to consultation held an upholstering tack in her mouth, which accidentally found its way into the lung. She choked and coughed up some blood, which was followed by a somewhat persistent cough with expectoration.

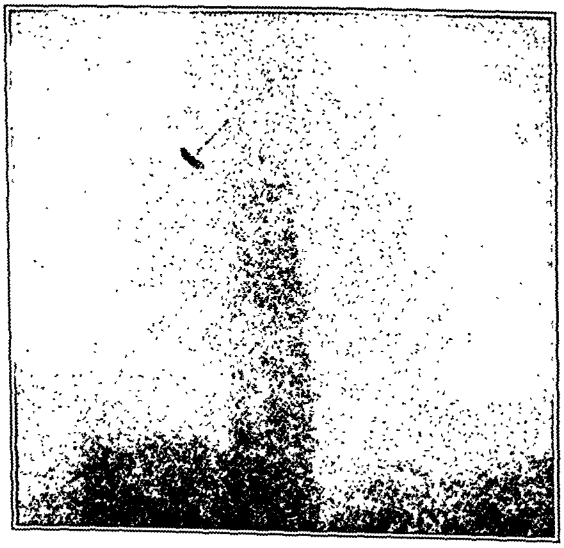


Fig. 1.—Tack in right main bronchus, three days after accident.

A roentgenogram (Fig. 1) had been taken three days after the accident, indicating the presence of the tack in the right main bronchus with the head downward.

There was absence of breath sounds in the upper part of the lung and râles below.

I expected to find the tack in the same position as seen in Figure 1, and did not have another roentgenogram taken, but immediately made a bronchoscopic examination, which revealed the following: About 5 mm. of the sharp end of the tack was seen in the right main bronchus, somewhat posteriorly to the right with the point downward and toward the midline, closely hugging the wall. It appeared as if it had been stuck through the wall from the outside, as there was no trace of the opening to the eparterial bronchus. The forceps was applied and many attempts were made to extract the tack, but the lower part of the lung was simply pulled up with it for a considerable distance before the forceps slipped off. Attempts were made to pull the tack downward but without success. The point could be brought up in the bronchoscopic tube but it required considerable force.

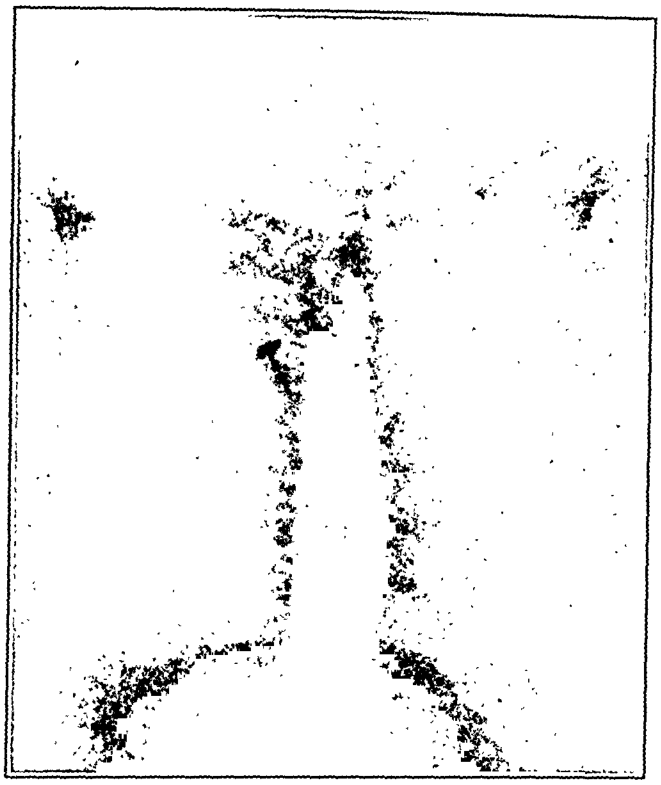

Fig. 2.—Tack in right eparterial bronchus, eight days after accident.

It was evident that the head was up in the side bronchus and that the swelling had completely occluded the lumen of the bronchus around the tack, on which epinephrin had no effect, so that forcible extraction could not be carried out without much destruction. After this attempt there was increase in the cough, pronounced hoarseness, and a temperature varying between 100 and 103.8.

Roentgenoscopy now showed the tack with the head up (Fig. 2), as seen through the bronchoscope.

I decided to incise the neck of the eparterial bronchus to liberate the tack, and to this end had the curved blade (A *b*, Fig. 3) made, which is worked by a lever (A *c*, Fig. 3).

Three days after the first attempt the incision into the neck of the bronchus was made through a 5-mm. bronchoscope. A gush of dark blood poured out, but ceased as soon as the bronchoscope was withdrawn.

The following day there was a marked change in the patient's condition. The temperature was normal, the hoarseness had disappeared, the cough had lessened and she felt very well although the tack was still in the bronchus.

As extraction of the tack was not attempted, and, I think, should not have been attempted in the same sitting, because it might have greatly increased the hemorrhage, I could not be positive that the incision had been sufficient. For the third sitting, therefore, two other methods of attack were prepared. Two long and very slender cannulas were made to fit on ordinary nasal snare handles. The right side of the distal end of one cannula was filed off slanting so that when the tack was snared it would be held as near parallel to the cannula as possible (B *a*, Fig. 3). With another snare one or more wires were to be slipped over the first one and on the tack (B *b-c*, Fig. 3). While one assistant would push downward the point of the tack securely held by the snare, another assistant should pull up on the loose wire, *b-c*. The head of the tack would thus be brought close to the bronchoscopic tube and as near the neck of the bronchus as possible, and with a short straight blade which was made for the purpose or with a cautery, the intervening part could be severed. This could also be done by using the wire as a saw or by threading it on the second snare and snaring it.

In Figure 3 C another method is shown in which by the aid of the snare, *b*, the point of the tack is pulled up into the bronchoscopic tube and with the cautery or knife the neck is to be incised.

Seven days after the incision was made a roentgenogram showed the tack in the same position as in Figure 2. Bronchoscopy likewise demonstrated the tack in the same place and the incision could be seen. When the forceps was applied, however, the tack was found to be entirely loose, and when it was lifted out it fell headforemost into the lower hyparterial bronchus, whence it was quickly picked up and removed.

The tack measured 18 mm. in length and the head 8 mm. in width (D, Fig. 3). The lung cleared rapidly and the patient left the hospital a few days later.

In the first roentgenogram (Fig. 1) the tack was apparently in the right main bronchus, point up, and with the head probably resting in the opening of the eparterial bronchus. By suction it had been advanced up into the latter (Fig. 2).

I have been unable to find any measurements of the eparterial bronchi in children, but according to Engel (*Arch. f. Kinderheilk.*, 1913, p. 60) the diameter of the right main bronchus in a child of 5 years is: sagittal 8.4 mm., frontal 6.9 mm.; in a child of 7 years is: sagittal 9 mm., frontal 9.3 mm.

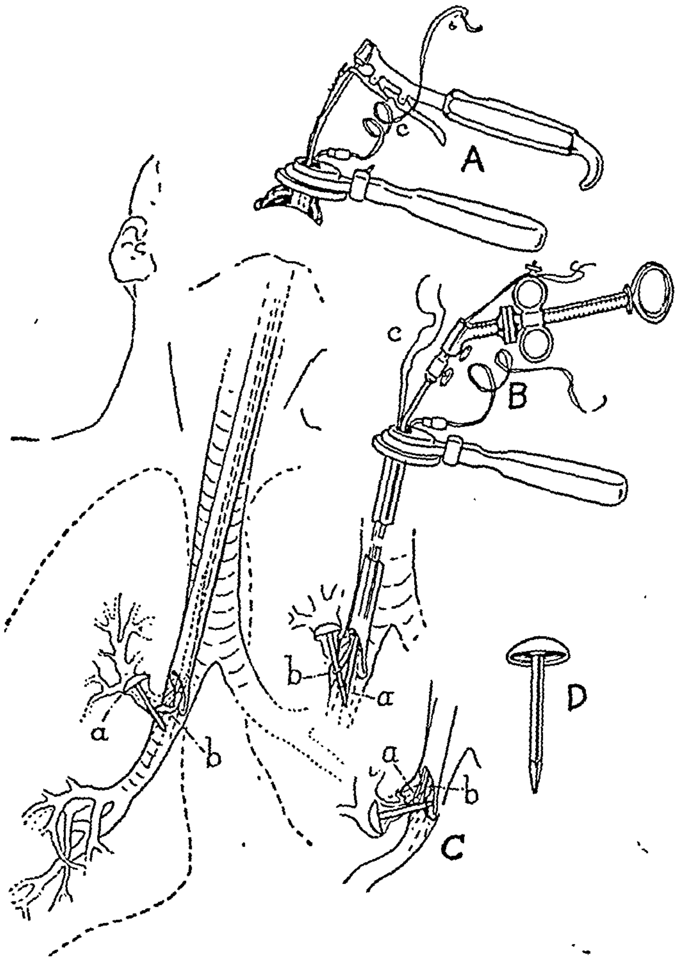

Fig. 3.—A: *a*, upholstering tack; *b*, curved blade; *c*, lever for working the blade. B: *a*, distal end of snare holding tack downward; *b*, *c*, wire for pulling head of tack upward. C: *a*, cautery; *b*, snare. D: Tack (actual size).

The length of the eparterial bronchus: at the age of 5 years 7 mm.; at the age of 7 years, 10 mm.

According to Abey, the diameter of the main right bronchus in men is: from 15 to 21 mm.; in women, from 13.5 to 16 mm. The diameter of the eparterial bronchus in men is from 7 to 10 mm.; in women, from 8.5 to 9 mm.

According to this, roughly estimated, the diameter of the eparterial bronchus would be about half of that of the main bronchus, and the eparterial bronchus in a child of 6 years would very likely be less than 5 mm. in diameter.

Allowing for the individual variation in size of the bronchi, it would seem almost incredible that so large a foreign body could work its way into a side bronchus of a child of that age, and it can readily be understood how firmly it was fixed in place.

A CASE OF CARDIOSPASM, WITH IMPROVEMENT IN METHOD OF DILATATION

T. Arthur Johnson, S.B., M.D., DeKalb, Ill.

History.—Dec. 12, 1912, an 18-year-old Finnish girl came to me complaining of being unable to keep anything in her stomach. The interpreter stated that she had not retained any liquid or solid food for over eight days. When she attempted to swallow anything it was immediately returned. This was accompanied by a burning sensation at the pit of the stomach, but the returned food did not taste sour. She felt hungry and dry, and had lost 10 pounds in weight. She had had similar, slight disturbances at intervals for about a year and at these times was relieved by drugs. The previous history is negative with the exceptions that she had an attack of acute articular rheumatism about a year before and she has always been "nervous."

Examination shows a fairly well-developed, neurotic appearing girl with very prominent eyes. The faucial and corneal reflexes are practically absent. The thyroid is slightly enlarged, but the pulse-rate is normal. The left border of cardiac dulness extends one finger's breadth to the left of the midclavicular line, the pulmonic second sound is accentuated and a loud systolic murmur is transmitted to the left axilla. There is slight tenderness on pressure over the epigastrium. The hemoglobin is 70 per cent., and the reds and whites are normal in number and type.

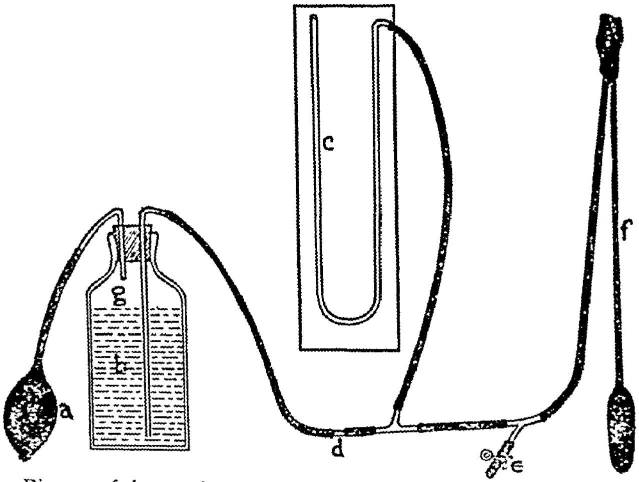

Diagram of the complete apparatus for dilating the cardia: *a,* hand-bulb of mercury manometer; *b,* water in pressure bottle; *c,* mercury manometer; *d,* glass capillary tube; *e,* emergency valve; *f,* Sippy cardiospasm dilator; *g,* compression chamber above water.

Treatment.—A stomach-tube reinforced with a piano wire was passed without resistance, and the patient was fed by gavage and placed on bromids and belladonna. In about one week she could swallow without any difficulty. Four weeks later she returned with the same symptoms. I passed a series of olive esophageal dilators into her stomach very easily, the largest one passing as easily as the smallest. At no time could I demonstrate but a small quantity of retained pabulum in the esophagus. At that time I did not have easy access to a Roentgen-ray apparatus.

Jan. 4, 1913, I dilated the cardiac sphincter with a Sippy rubber bag dilator up to 150 mm. of mercury. The patient was free from her trouble for two weeks. At the return of the cardiospasm I again dilated the sphincter to 300 mm. of mercury without causing any pain. Since then there has been no recurrence of her cardiospasm.

IMPROVEMENT IN METHOD OF DILATATION

In connection with the report of this case I wish to present a slight improvement in the method of forcible dilatation of the cardiac sphincter by means of the rubber balloon dilator. The apparatus used is a combination of the ideas of the pioneers in this work, with the innovation consisting in generating the dilating pressure by compressing the air-chamber of a tightly stoppered bottle—partly filled with water—by means of the hand bulb of a mercury manometer.

With the apparatus arranged as in the diagram, the rapidity of increase and the amount of pressure are at all times under complete control of the operator. The pressure generator can be easily constructed and is extremely portable. The small capillary tube *d* inserted into the lumen of the rubber tube is a further safeguard against too rapid dilatation, and the emergency valve *e* provides for instant release of the water pressure in case that becomes necessary. This provides a more simple, easy and safer method of obtaining the pressure than any that has come within my knowledge.

Therapeutics

PREVENTION IS GREATER THAN CURE

(*Continued from page 2043*)

XI

AIR CONTAMINATION

Normally the alveolar air of the lungs, that is, the air retained in the lungs for oxygen and carbon dioxid (CO_2) exchange, contains about 5 per cent. of the latter. If the amount of this gas in the retained air is diminished below 5 per cent., breathing is slowed until the carbon dioxid has accumulated and this percentage is again reached. If the percentage of the carbon dioxid is increased above 5 per cent. the respiration becomes more rapid, until the amount again becomes normal.

The arterial blood leaves the lungs with the same percentage of carbon dioxid in it as is in the alveolar air, and this carbon dioxid content of the blood stimulates or depresses the respiratory center, depending on the amount of the carbon dioxid in the blood. Therefore, this gas is a regulator of the respiration. Exercise increases the carbon dioxid, and hence the respiration is increased.

The alveolar air contains about 16 per cent. of oxygen, and the red blood-corpuscles in the blood of the left heart normally contain all they will absorb. Crowder[1] says that if the oxygen is diminished in the lungs to 12 per cent. or less the corpuscles will still take up their full quota. He also states that neither a surplus nor a deficiency of oxygen in the air supplied the lungs, unless the difference is extreme, will cause a change in the oxygen content of the red corpuscles. Actual need of oxygen will not increase respiration if at the same time the carbon dioxid in the alveolar air is reduced; that is, the carbon dioxid must equal 5 per cent. for normal respiration to occur. He emphasizes the fact that "with each breath we take back into the lungs the air contained in the nose and larger bronchi

---

[1] Crowder, T. R.: On the Reinspiration of Expired Air, Arch. Int. Med., October, 1913, p. 420.

—the 'dead-space' air. This 'dead-space' air constitutes about one-third of the whole volume of quiet inspiration and not less than one-tenth of deep breathing. To all intents and purposes it is expired air which is constantly reinspired."

Hence the degree of contamination of the air in a room with carbon dioxid does not affect the individual, but the amount of water vapor does. It is not rebreathing the same old air, either of our own breath or of others, that mainly affects us, but it is the water vapor which prevents the air exchange on the surface of our bodies, and especially stagnant, overmoist air, that depresses and debilitates us.

Crowder has fully shown that we rebreathe our own inspired air over and over again. Hence it is not pure air we breathe. This is true when at rest, true when in bed, especially true in some confined sleeping positions. It is true with open windows, and in most tents and on verandas, and even in actual open air, unless the wind blows freely across our faces. In the latter case the depth of the breathing is reduced, and we might reexchange the air of the upper air passages more or less all night even while sleeping with the face exposed to the wind.

None of this militates against the value of clean, fresh air as a stimulant to the metabolism, and therefore to health, but it does show that the chemical constituency of the air is not primarily important, while the temperature and moisture are. Dry, cool air is bracing; dry warm air, if in motion, may be comfortable and not depressing; but warm, moist stagnant air is very depressing to metabolism, and hence when such a condition occurs in houses, stores, factories or assemblage halls harm is done to the individual in amount depending on the hours he spends in such an atmosphere. Overheating of houses and schoolrooms is harmful; too great humidity is also bad, although a too dry atmosphere is not desirable.

DISSEMINATION OF CONTAGION

The wonderful progress in medicine is in no way shown more than by the knowledge acquired by the bacteriologists and by the wonderful experimental work of the laboratory workers. The various funds devoted to this work are paying large dividends in preventive medicine. Experimentation with the higher animals which more closely resemble human beings has disclosed many truths hitherto unknown regarding pathology, bacteriology and contagious diseases.

It was formerly believed that infectious material, which was not then known to consist of micro-organisms, was carried through the air for considerable distances. With small-pox it was believed that infection could travel several thousand feet. It has now been shown that this disease cannot pass through the air more than a few feet.[2]

Infectious material from patients suffering from disease of any kind may adhere to clothing, furniture, books and similar articles and may be carried from one person to another and be a means of infecting other individuals, but this method of transmission is at the present time believed to be uncommon. Ordinarily a contagious disease is acquired by direct contact and largely by the patient breathing in germs or particles of infected matter which have been expelled from the person affected with the disease by sneezing, coughing, or even loud talking.

A frequent means of transmitting disease from one person to another is by so-called "missed cases," that is, patients who have the disease in such a mild form that it is not recognized. This is especially likely to happen with diphtheria and scarlet fever. Another frequent source of acquiring disease is by means of so-called "carriers," that is, persons who have in their throats or other parts of the body the micro-organism of a disease, but who do not know they have the disease and are not made ill by the germs.

Some pathogenic bacteria die so quickly after leaving the body that infection from dust or air contaminated by them is practically impossible. Such are notably the germs of influenza, cerebrospinal fever and gonorrhea. In these diseases direct contact is the only probable method of transmission. This does not detract from the fact that not infrequently contagion is conveyed to well persons who come in contact with mucus or mucopus containing living germs.

Tubercle, diphtheria and typhoid bacilli, on the other hand, may survive drying and be wafted in the dust, but infection by means of such dust is probably very rare. Droplet contamination of air and of articles immediately about a person infected with pulmonary tuberculosis or diphtheria frequently occurs.

The air of sewers has been shown to contain few pathogenic organisms, except in very rare instances. A few colon bacilli have been found, but then in such small numbers that the danger of infection from inhaling such gas is practically nil.

Even if the dust of a room is shown to contain viable tubercle or typhoid bacilli, the number of such in the upper air of the room would ordinarily be so few that infection in this way is practically impossible. Young children playing about the floor of such a room, however, would be in danger of infection, and infection with tuberculosis in children is doubtless frequently thus acquired.

Investigation seems to show that the pathogenic bowel germs are rarely air-borne, and that the infection cannot be thus acquired. Such germs are those of typhoid fever, paratyphoid fever, dysentery, diarrhea and cholera. Typhus fever is not air-borne, but is due to the bites of the infected body- or head-louse. Bubonic plague is transmitted by the bite of an infected flea.

The rapidly spreading influenza (the grip) seemed surely to be disseminated by dust or to be air-borne, but it seems that, like tonsillitis, diphtheria and ordinary colds, it is contracted by contact either with the infected person or with contaminated substances, as clothing, handkerchiefs, furniture, eating and drinking utensils, etc. The same is true of eye inflammations and contagious skin diseases. This has long been known to be true of syphilis and gonorrhea.

Much more difficult for medical men, to say nothing of laymen, to believe is what must now be considered a fact, namely, that the scales of desquamating scarlet fever are not contagious and do not carry the contagium; scarlet fever is spread only by contact with the infected person or with articles infected by the patient having the disease.

Measles, apparently the most readily spread of any contagion, seems to be transferred only by contact. It was suspected that this disease was transmitted by the air because a child could disseminate it so many days before he was actually sick and confined to the house or bed. Whooping-cough, "German measles" and chicken-pox are all probably spread by contact and not by diffusion through the air. Small-pox, as stated above, is spread only by contact.

---

[2] Kiefer, G. L.: The Control of Contagious Diseases in a Municipality, The Journal A. M. A., Dec. 7, 1912, p. 2022.

It has been shown in hospitals that if the nurses are careful not to allow contact with other patients, small-pox, measles and scarlet fever, the most contagious of all diseases, may be cared for in adjacent wards, and even, in careful experiments, in adjacent beds, without infection of others. Of course, such close association of a contagious disease with those who have not the disease is absurd on account of the failure, in the routine work, of nurses and attendants to carry out strict measures to prevent contact or the transmission of contaminated articles from one to another. Therefore, there should be separate wards, if not separate buildings, for the different contagious diseases; but the experimentation mentioned above shows conclusively that these diseases are spread by contact only.

It is now recognized in hospital operating rooms that droplet infection is a danger, if all other sources of infecting the wound are excluded, and hence surgeons and their assistants wear mouth and nose covers lest they cough, sneeze or speak energetically, and thus spray the region of the wound.

It is hardly probable that pneumonia and acute rheumatism can be spread in any other way than by contact. It is possible that these more or less constantly present germs may require only a certain condition of the mouth, upper air passages and system to infect us. Cerebrospinal fever and infantile paralysis doubtless require contact, and are probably not air-borne. It should also ever be remembered, in considering the possibility of an air- or dust-borne infection, that it requires a large number of most germs to cause an infection; a few would ordinarily be killed off before infection could occur.

FLIES

The ubiquitous fly is a menace and a distinct and positive source of danger. He can disseminate typhoid, diarrhea and dysenteric germs, and probably also the germs of tuberculosis, diphtheria, scarlet fever, cerebrospinal meningitis, small-pox, carbuncle, tetanus, rabies, anterior poliomyelitis, and even germs from granular lids. Also these insects can harbor, for long periods, in their bodies the various pathogenic germs. Frozen flies from a hospital, after being externally cleansed and dried and then powdered and cultured, have been shown to harbor staphylococci, streptococci, colon bacilli and about fifty other kinds of bacteria. Experiments have shown that when a fly is fed on such bacteria as the typhoid bacillus and streptococci, and later cultures taken from its dead body, these cultures will show pure growths of the bacteria on which the fly was fed.[3] Consequently, not even a dead fly is a good one, and all dead flies should be cremated if not washed down the sewers.

House and stable flies are not supposed to stray ordinarily more than 500 yards from their breeding-places, but winds may carry them farther. It should be regarded as an axiom that all breeding-places (manure heaps and filth) should be abolished, or receive such treatment as to prevent the growth of the flies, and in this object there should be cooperation of families, tenement owners, towns and cities.[4]

Infected flies may be readily carried on horses or in vehicles of all kinds for long distances, and may be the source of infection of patients far removed from the contagion, and the transportation of germs by flies doubtless accounts for many new foci of disease.

MALARIAL FEVERS

Thousands of lives are lost in the United States from malarial fever, and many thousands of persons are incapacitated for days and weeks by such fevers.

Although the subject of mosquitoes has already been touched on, it may be again emphasized that the public should know, and children in schools should be taught, that the anopheles mosquito, which inhabits swampy places and does not ordinarily fly far, and only comes out of its lair and bites at night, is the only source, as far as we know, of what is termed malarial fever.

This mosquito is innocent of harm until it has sucked blood infected with malarial plasmodia, capable of development, from a human being. When these germs develop into spores and are excreted by the mosquito's salivary glands she is able to infect an innocent human being. The female mosquito will harbor these germs until she dies, unless she is subjected to a temperature below 60 F. Hence in regions where the temperature falls below this point for a shorter or longer period, these infected mosquitoes are no longer able to infect human beings. The source, therefore, of the next season's infection is in human "carriers" of malarial germs, in most parts of our continent, except where it is always warm.

The question, then, is, Can we eradicate malarial plasmodia from human beings? Probably yes is a correct answer if we follow what has been scientifically ascertained, namely, that quinin in proper dosage will stop acute malarial fever in two or three days. But as this quinin destroys only the asexual forms, that is, the form that causes paroxysms, while the sexual or reproductive forms may live and redevelop for infection of the mosquito, or to cause a reinfection and symptoms in the patient, the drug should be again given for two days of each week for a period of eight weeks to be sure of complete elimination of the germ; or it may be as well to give the patient a daily dose for eight weeks to eradicate the germs and their spores completely and to prevent the infection of future mosquitoes. If every physician carried out this plan, and every patient allowed it, malarial fever would become unusual.

It may again be mentioned that kerosene or crude petroleum sprayed on stagnant water or wet places will prevent the development of mosquitoes. One ounce of kerosene will cover 15 square feet of water surface: Stagnant water should not be allowed.

(To be continued)

Birth- and Death-Rates.—Records of the Department of Health show that for the past six years the birth-rate of New York City has been steadily decreasing, and that last year the lowest point for the six years was reached. The death-rate had likewise decreased steadily, so that to-day the births exceed the deaths by eleven per 1,000. This city has the second lowest mortality figures among the cities of the world which have a population of 2,000,000 or more. The birth-rate here is 25.15 per 1,000, while in London it is 24.93 and in Berlin 19.61. The death-rate exceeds only that of Berlin, which is 13.48 per 1,000. The deaths from pulmonary tuberculosis number 1.601 per 1,000, while in Paris they are 3.178. Paris has also the highest mortality from typhoid fever.

THE PROPER DOSAGE OF DIPHTHERIA ANTITOXIN

At the last session of the American Medical Association, Dr. W. H. Park[1] read a paper in which he reported his experience with Schick's[2] test. This reaction indicates whether or not persons who have been exposed to diphtheria are susceptible to the disease; that is, whether or not prophylactic injection of antitoxin is needed. In the discussion, it was urged that the matter be brought to the attention of physicians as soon as possible, in order to avoid the expense and inconvenience of unnecessary prophylactic inoculations.

Some later studies of Schick[3] which bear on the dosage of diphtheria antitoxin in the treatment of diphtheria patients have recently been reported from von Pirquet's clinic in Vienna. They seem to be of such practical importance for the every-day work of general practitioners as to make it desirable that every physician should become acquainted with them. While all special workers will want to read the full details of the experimental work which has led to Schick's conclusions, in general, it will be sufficient to know the results and that the methods by which they have been reached indicate that we have good reason to believe in their reliability. It is interesting to see how closely the results obtained by Schick correspond to those which followed the careful studies of Park on toxin and antitoxin titration in diphtheria.

Schick and his associates have made use of the now well-known fact that intracutaneous test injections of minimal amounts of diphtheria toxin will cause redness and swelling at the site of injection. In diphtheria patients, they made several such intracutaneous test injections at three-hour intervals for some little time preceding the moment of injecting the curative antitoxin. After injecting antitoxin, they subsequently made intracutaneous test injections of the same minimal amounts of diphtheria toxin at twenty-four hour intervals. The curative dose of antitoxin was given intramuscularly, and varied in size in different patients. The effect of the antitoxic serum is precisely recognizable by the decrease in the diameter of the reactions following the intracutaneous test injections of toxin.

Careful observation showed that the main effect of the antitoxin is one of immunization — that is, a suitable dose of antitoxin renders the individual immune to a dose of toxin administered later. On the other hand, even a large dose of antitoxin has but slight effect on the action of toxin injected previously. To be sure, there is some effect on toxin introduced from three to six hours before the injection of antitoxin, and in exceptional cases an enfeeblement of the effect of the toxin introduced nine hours before the antitoxin was given; in other words, the main effect of antitoxin injection is to protect against toxin arriving after the antitoxin has been introduced.

The experiments have shown that it is necessary to calculate the dose of antitoxin according to the body weight of the patient. When amounts of antitoxin corresponding to 50 units per kilogram[4] of body weight are given, the protective effect against toxin injected simultaneously, and on that injected twenty-four hours later, is demonstrable, but is not satisfactory. On increasing the dose of antitoxin to 100 units per kilogram, the immunizing effect is extraordinarily better, as, in the majority of cases, toxin injected twenty-four hours later produces no effect whatever. In addition, the effects on toxin injected simultaneously is much better than when only 50 units per kilogram are given. On increasing the dose of antitoxin to 250 or to 500 units per kilogram, the influence on simultaneously injected toxin is somewhat improved, but there is no increase whatever in the immunizing effect, for, as has been said, 100 units per kilogram exert a maximal effect on any toxin subsequently introduced.

Further observations showed that a maximal antitoxin effect is obtained with a dosage of 500 units per kilogram; larger doses have no greater influence, either on simultaneously injected toxin or on toxin injected twenty-four hours afterward. The retroactive effect on toxin injected three hours earlier is very slight even when 500 units per kilogram are given, and such large doses have only a slightly better effect than doses of 100 units per kilogram.

In the treatment of human diphtheria, therefore, Schick and his colleagues recommend (1) that the injection be given at the earliest possible moment; (2) that it be given intramuscularly; (3) that in all mild and medium cases of diphtheria (and these make up about 90 per cent. of all cases) a single dose of 100 units of antitoxin per kilogram suffices, and (4) that in the severest cases, 500 units per kilogram may be injected. In other words, in a child weighing 20 kg.

[2] Schick, B.; Kassowitz, K., and Busacchi, P.: Experimentelle Diphtherie Serum-Therapie beim Menschen, Ztschr. f. d. ges. exper. Med., 1914, iv, 83.

[3] An Early Test for Susceptibility to Diphtheria, Editorial, The Journal A. M. A., April 11, 1914, p. 1176.

[4] A kilogram is equal approximately to 2⅕ pounds avoirdupois.

(or 44 pounds), 2,000 units will, in 90 per cent. of the cases, suffice, while in 10 per cent. of the cases of the most severe type a dosage of 10,000 units may be given. In an adult weighing 60 kg. (or 132 pounds) a dose of 6,000 units will suffice in all the ordinary cases, whereas in the severest cases a single dose of 30,000 units may be given.

One of the most important of Schick's observations is that repeated injections of the serum are superfluous and not warranted. Even in the severest cases, he asserts that if a dose of 500 units per kilogram be injected immediately the greatest good possible will be obtained. Subsequent injections of antitoxin after six, twelve or twenty-four hours are, he maintains, unnecessary, for any further effect of toxin is prevented by a single dose of the size mentioned. If the diphtheria patient dies, it is because the toxin elaborated by the organisms in his body has had time to act before the antitoxin was injected, and cannot by any means as yet known to us be afterward inactivated. The only circumstance in which a second injection is of value is when the first injection given has been smaller in dose than the optimal doses recommended; then one may give a single dose of 500 units per kilogram.

In exposed persons requiring a prophylactic immunizing dose, a single injection of 50 units per kilogram is sufficient.

If the conclusions drawn by Schick and his colleagues from these interesting studies be correct, it is obvious that the practitioner will, from now on, be provided with a precise method of treating diphtheria patients hitherto much desired. It would appear that the enormous doses sometimes given of 100,000 units, or more, of antitoxin are wholly unnecessary, involving large expense and much inconvenience to the patient, especially where repeated injections have been given. One would, of course, not shrink from the expense or from the inconvenience, could a single life be saved thereby; but Schick's studies seem to indicate that in most cases 100 units per kilogram, and in a few severest cases 500 units per kilogram, given in a single dose, yield the maximal protective effect at present obtainable.

THE NATURE OF THE NERVE IMPULSE

Many views have been advanced with regard to the nature of the conduction processes in nerves. Naturally so fundamental a phenomenon as the passage of an impulse along a nerve cannot fail to awaken speculation on the part of anyone who is accustomed to think critically about physiologic processes. With the accumulation of new facts bearing on the question old theories have been abandoned and new hypotheses in turn advanced. The mere review of some of these is of interest as an illustration of the way in which science sometimes progresses. Thus, it has been suggested that the whole nerve moved like a bell rope; that the nerve was a tube, and that a biting acid flowed along it; that the nerve contained an elastic fluid which was thrown into oscillations; that it conducted an electric current like a wire; that it was composed of definitely arranged electromotor molecules which exerted an electrodynamic effect on each other; that it was made up of chemical particles which, like the particles of powder in a fuse, underwent an explosive change, each in turn exciting its neighbor; that the irritant caused a chemical change, which produced such an alteration of the electrical condition as to excite the neighboring parts to chemical change and thereby to electrical change, and so alternating chemical and electrical changes progressed along the fiber in the form of a wave; finally, that the molecules of the nerve substance underwent a form of physical vibration analogous to that assumed for light.[1]

Even at present, students of the subject are still divided into two camps, one of which inclines to a physical theory of nerve conduction, the other to a metabolic or chemical theory. We know, at any rate, that there is no mechanical change in the nerve. If the nerve serves merely as a conducting medium in a purely physical sense, one would not expect much, if any, expenditure of energy in the process. The lack of any heat production in stimulated nerves[2] appears like decided evidence against the idea that irritability is primarily a chemical phenomenon. Heat changes are characteristic of metabolism. On the other hand, convincing evidence has gradually accumulated tending to show certain small chemical changes incident to the excitatory processes in nerves from the fact that, in the complete absence of oxygen, the nerve fibers lose their irritability, and that the latter may be restored by readmission of oxygen to the nerve.

By the use of an ingeniously contrived apparatus, the biometer, in which amounts of carbon dioxid as small as 0.000,000,1 gm. can be measured, Tashiro[3] has demonstrated in the laboratories of the University of Chicago not only that all living nerves give off carbon dioxid—a sign of chemical change—but also that their metabolism increases on stimulation. These facts have now been supplemented by Tashiro and Adams[4] in harmony with the argument that the primary basis of protoplasmic irritability must be a chemical one. Their new evidence shows that, in the absence of oxygen, nerves have a far lower output of carbon dioxid than in air, and that stimuli which more than double the output in air fail to give any increase in an atmosphere of hydrogen, that is, an oxygen-free medium. Oxygen is therefore primarily concerned with the metabolism of nerves.

4. Tashiro, S., and Adams, H. S.: Carbon Dioxide Production from the Nerve Fiber in a Hydrogen Atmosphere, Am. Jour. Physiol., 1914, xxxiv. 405.

The foregoing facts are no proof that oxidative change or metabolism in the nerve is the forerunner or cause of its conductivity. They might, of course, express the effect of the change in the state of excitability. Whatever the future may finally say to the question whether nerve fibers can function independently of chemical changes, it now seems certain that active metabolism in the nerve fiber is a fact; and, quoting the Chicago investigators, the incorrect assumption of an absence of metabolism can no longer be used by the physical school to support their argument.

ACETYLCHOLIN AND ERGOT PREPARATIONS

Some time ago, in a discussion of the active principles of ergot,[1] attention was called to the discovery by the pharmacologist Dale and the chemist Ewins of acetylcholin in certain preparations of ergot. The physiologic action of this base had already been investigated by Hunt and Taveau,[2] who pronounced it to be far the most powerful circulatory depressant known. Its occurrence, therefore, in preparations of ergot intended for medicinal use naturally aroused considerable interest, for the question arose whether it might not add to the dangers of this drug. Dale[3] now reports an extensive study of this and of some other derivatives of cholin. He confirms the observations of Hunt and Taveau as to the extraordinary activity of this substance; indeed, he finds it even more active than did these authors, for whereas the latter found 0.000,005 mg. injected intravenously into a rabbit to cause a fall of blood-pressure, Dale reports such a result from "the almost incredibly minute amount of 0.000,001 mg. (the one-millionth part of a milligram)."

Fortunately this extraordinarily active substance is only exceptionally found in medicinal preparations of ergot, and then as a rule only in minute amounts; still Dale found as much as 0.2 mg. per cubic centimeter in one such preparation. This amount injected intravenously into a human being would undoubtedly cause most alarming symptoms; it would be harmless by the mouth and probably if given subcutaneously, for acetylcholin is rapidly destroyed in the tissues. In these days when the administration of drugs intravenously is increasing and when manufacturers are placing so many new preparations for such use on the market it would be well for a physician considering this use of an ergot preparation to bear in mind the possible occurrence in it of acetylcholin. There are no chemical tests by which this substance, even when present in dangerous amounts, can be recognized, but there are physiologic tests by which the most minute amounts may be detected. Any preparation of ergot intended for intravenous use should be subjected to these tests; it might be well also to test those prepared for subcutaneous use, for Hunt and Taveau found doses of 0.1 mg. injected subcutaneously into cats to cause a pronounced fall of blood-pressure.

Aside from this practical aspect of the occurrence of acetylcholin in ergot, the substance itself is of much scientific interest. It is easily prepared from cholin and certain simple derivatives of acetic acid. Cholin is probably a constituent of all living cells; it has been found in the blood and in all organs investigated (beginning with its discovery in the adrenal glands by Hunt in 1902). The animal body always has derivatives of acetic acid available for synthetic purposes; when benzoic acid, for example, is taken it is quickly excreted as hippuric acid, that is, as a compound of benzoic and amino-acetic acids. May not conditions arise in the body under which cholin may unite with acetic acid to form acetylcholin just as this substance is formed by the fungus of ergot? Or is it not possible that the body itself may form such a compound for some of its own purposes just as it forms epinephrin? Some of these questions were raised by Hunt several years ago and are again brought up by Dale. As Dale states, we have in epinephrin a substance having a special affinity for one great division (the true sympathetic) of the autonomic nervous system; it is formed in the body and utilized by it for the purpose of stimulating the endings of the nerves of this system. Acetylcholin, on the other hand, has little or no effect on the true sympathetic nerves, but has a specific action on the other great division of the autonomic nervous system—the cranial and sacral (or parasympathetic) division, which supplies the sphincter of the iris, the inhibitory nerves to the heart, the motor and secretory nerves to the alimentary tract, etc. Epinephrin is a very unstable substance; it is secreted, under certain conditions, by the adrenal glands, fulfils its physiologic functions and is then destroyed. Acetylcholin is a more active substance, but in a different way, than epinephrin; it is even more readily destroyed. May it not function as a hormone in the same, but in a complementary or antagonistic way, as does epinephrin? Its instability may have prevented its detection just as the secretion of epinephrin was long overlooked. As Dale says, these questions are of great interest, but for the discussion of which little evidence is at present available; there is no known depot in the body of cholin derivatives as there is in the case of epinephrin, or indeed any evidence that a substance resembling acetylcholin exists in the body at all. It is true, as Dale recalls, that Hunt[4] found evidence of the existence of a substance in the suprarenal glands which was not cholin itself, but which readily yielded cholin in the process of extraction, and which was from fifty to a hundred times as active as cholin; the nature of this substance has not, however, been determined.

[2] Hunt and Taveau: Hyg. Lab. Bull. 73, U. S. P. H. S., 1911; Brit. Med. Jour., 1906, ii, 1788.

[3] Dale: Jour. Pharmacol. and Exper. Therap., 1914, vi, 147.

[4] Hunt: Am. Jour. Physiol., 1899, iii, 18; 1901, v, 11; Brit. Med. Jour., 1906, ii, 1788.

This work illustrates some of the lines of work in modern pharmacology; the results are of immediate practical as well as scientific interest. The best results are obtained when a pharmacologist can cooperate with a skilled organic chemist. It is unfortunate that there are not more laboratories in this country where such cooperation is possible.

LOSS OF LIFE BY EXPLOSIONS IN THE MILLING INDUSTRY

Statistics sometimes surpass all forms of direct argument in emphasizing the need of reforms relating to the public health. In this belief we cite from a preliminary report published by the Millers' Committee of Buffalo[1] the fact that in thirteen investigated explosions which have occurred in grain mills and similar industrial plants in very recent years in this country, at least seventy-eight men were killed and 119 injured. Incidentally, the total damage to property exceeded $2,000,000. In four explosions in Europe since 1911 — two in dextrin works, one in a provender mill grinding peas, beans and wheat, and one in a linseed mill — the human loss is expressed by forty-seven killed and 119 injured.

Surely some consideration of methods pertaining to the prevention of such explosions is called for. It has already developed from Dr. Brown's laboratory study of the problem[1] that most, if not all, grain dusts are more inflammable than standard coal dust (which has long been recognized as a source of danger in the industries). Grain dusts in most cases develop higher pressures on explosion, especially at the lower temperatures. The preliminary observations seem to indicate that the dusts from oats and yellow corn are more inflammable than those from wheat and other grain.

The investigations of the Millers' Committee indicate a difference in the inflammability of dried and undried dusts. In nearly every case the pressure developed on explosion was increased appreciably after drying. The result of a decrease in the humidity of the air is thus suggested.

Various causes have been assigned to many of the explosions in milling plants in this country and abroad, among them the use of open lights, or naked flames, such as lamps, torches, gas jets, lanterns, candles, matches, etc.; property fires; introduction of foreign material in grinding machines; electric sparks from motors, fuses, switches and lighting systems, and static electricity produced by friction of pulleys and belts, grinding machines, etc.

The field-engineering inquiries of the Buffalo investigators indicate that a large number of the recent explosions and fires have been caused by the introduction of foreign material into grinding machines. It would appear that a possible means of prevention would be to devise some system by which the foreign material might be removed before it reached the mill. For the present, it is recommended in a practical way that prevention of explosions may be assisted by complete electric-lighting systems, the use of portable electric lamps instead of lanterns or naked lights, the enclosing of the electric-light bulbs in strong wire guards or protectors, and the possible use of vapor-proof globes, and the locating of all fuses, switches, starting-boxes, motors, etc., at points where no dust is present. It is also advised to have the receiving bins from the grinding machines as small as practicable with the operations, as increased size gives increased space for dust clouds and, therefore, opportunity for a more violent and destructive explosion.

THE MOVEMENTS OF THE VILLI OF THE SMALL INTESTINE

In addition to their epithelial covering and their vascular and lymphatic arrangements, the villi of the small intestine contain masses of unstriated muscle fibers. These pass up from the muscularis mucosae through the villus, to be attached partly to the outer surface of the central lacteal, partly by expanded extremities to the basement membrane covering the surface of the villus. This combination of contractile structures, of which some run longitudinally along the lacteal spaces and others circularly about them, appears to afford an efficient mechanism whereby pressure can be exerted on the contents so that they are pumped into the communicating lymph spaces. Contractions of these muscle fibers are thus believed to tend to empty the central lacteal into the deep plexus of lymphatics and perhaps also to cause an expulsion of the contents of the spaces of the retiform tissues of the villus into the central lacteal.

For the most part the description of the function of the muscular mechanism of the villus has been limited to probabilities suggested by the facts of its anatomic structure. Direct observations of the motion of intestinal villi have lately been made by Hambleton[1] in the physiologic laboratory of the medical department of Vanderbilt University of Nashville. In animals that have been fasting the villi are generally found, on suitable microscopic examination, to be extended, fallen over in various directions, and covered with a mucus-like substance. Local application of solutions of a great variety of substances, for example, peptone, glucose, bile, saline, etc., is promptly followed by a rising of the villi and the beginning of lashing-like movements in various directions. Soon a second distinct movement begins, consisting in an alternating shortening or retraction and an extension of the villi. These movements are independent of peristalsis. They may be checked by local application of 0.1 per cent. hydrochloric acid and influenced by the introduction of drugs into the circulation.

---

[1] Brown, H. H.: The Explosibility of Grain Dust, Jour. Indust. and Engin. Chem., 1914, vi, 934.

[1] Hambleton, B. F.: Note on the Movements of the Intestinal Villi, Am. Jour. Physiol., 1914, xxxiv, 446.

The observations, which have been quite constant on all animals examined, lead Hambleton to conclude that the "lashing" movements, which are not stopped by atropin, may aid in the mixing of the intestinal contents and thus promote the action of the digestive secretions as well as the process of absorption. The other forms of movement—retraction and extension—are probably of special value in the act of absorption, particularly through the lacteals. This type is abolished by both nicotin and atropin, a sign that it is under the control of the peripheral nervous mechanism. It seems strange that activities which can apparently be observed so easily have attracted so little attention on the part of investigators.

Current Comment

ARE THERE EXPECTORANT DRUGS?

When one stops to consider the prescriptions of alleged expectorants which are written literally by the hundreds day after day it may seem somewhat captious to ask whether the practice has any admitted scientific basis. Expectorants have been defined as agents which facilitate the removal of secretion from the air passages. This is accomplished by the movements of the cilia in the bronchial passages, by the act of coughing, or by the combined action of these agencies. The expectorant can facilitate the desired process by inducing a more abundant secretion into the respiratory passages or one which serves to dilute, as it were, a tenacious mucus and render it more easily transported out of the recesses to which it adheres. An even more effective participation in the expectorant process lies in the possibility of stimulating the musculature of the bronchi and thus accelerating the mechanical features of the act. By analogy this might be looked on as a sort of peristalsis of the contractile tissues involved. Wherever one turns, in the text-books and scientific journals, there is an extreme dearth of trustworthy information as to the mode of action of even the most widely used expectorants. This fact has been emphasized anew by Miller[1] of Chicago, who has searched for accurate bedside observation on the value of this class of drugs. The present situation may be summed up by admitting that the bedside study of the action of expectorants offers at present insurmountable difficulties. Admixture of saliva, the loss or gain of water in the respiratory tract, and other factors influencing the amount and viscosity of sputum, apart from the spontaneous changes that may occur as an incident of disease, offer variables too complex to untangle in human patients. Observations on animals, particularly on the exposed bronchial mucosa, have furnished the chief reliance for evidence of positive effects.[2] Miller has interpreted the available results with the conclusion that ammonium carbonate and ammonium chlorid and the emetic group of expectorants, as apomorphin and ipecac, when given in sufficiently large doses to animals, increase bronchial secretion. Ammonium salts by mouth in moderate doses do not increase bronchial secretion in the dog. Apomorphin and emetin when given to dogs in quantities considerably greater than the ordinary therapeutic dose for man do not excite increased bronchial secretion. In view of so much negative evidence it may be worth while again to investigate the evidence on which is based the custom of giving this class of drugs.

THE COLLOIDAL GOLD REACTION IN EXAMINATION OF THE CEREBROSPINAL FLUID

Within recent years the examination of the cerebrospinal fluid has become of importance in conditions in which the meninges are involved, particularly if syphilis of the central nervous system is suspected. The information thus obtained is valuable as an index to the efficiency of treatment and also as an aid to diagnosis. The value of the Wassermann test and of determination of the cell-content of the cerebrospinal fluid in such cases is established. Abderhalden's method for the detection of certain ferments has not been perfected to the point which makes it practical for general diagnostic purposes in this field. The importance of the colloidal gold reaction, otherwise known as Nonne's or the gold chlorid test, has been recognized for some time, but until recently few have known within what limitations its value lay. It is essentially a test for an increase in the globulin content of the cerebrospinal fluid, using delicate color reactions in a standardized solution of colloidal gold as an indicator. The requisites for the test are cerebrospinal fluid obtained without a trace of blood, scrupulously clean glassware, and a colloidal gold solution prepared with extreme care. With these essentials at hand the performance of the test is comparatively simple. Miller and Levy[1] give explicit directions for preparing the solutions and performing and interpreting the results, together with an extended series of observations in which the results of Wassermann test on the blood and cerebrospinal fluid, cell and globulin estimation on the fluid and the colloidal gold reaction are compared in a great variety of clinical conditions. These tables show that normal cerebrospinal fluid gives negative reactions, but that in inflammatory conditions of the meninges, as tuberculous and purulent meningitis, the test is positive; hence it is of no value in distinguishing between these and syphilis. The reaction is inconstant in secondary and tertiary syphilis, and has no advantages over other diagnostic procedures in these conditions. The evidence seems to show that the colloidal gold reaction is most constant in general paresis and hence will be found of most value in the differentiation of this condition from others with which it might be confused. The authors suggest that this test may be found more sensitive than others now employed for indicating the results of specific therapy in syphilitic diseases of the central nervous system. The report is an example of what should be done with every new procedure either curative, prophylactic or diagnostic. Tests should be made in large numbers of diverse conditions and conservative conclusions drawn from the results as to the value and limitations of the procedure in question.

SUGAR UTILIZATION BY DIABETIC ORGANS

The successful employment of surviving organs of the body in the study of the functions of the living cells has given an impetus to the investigation of problems which seemed impossible of attack by the older methods. Glandular structures like the kidneys, muscles like the heart, and complexes of tissues like the intestines—all continue their usual performances for some time when they are supplied artificially with aerated blood or physiologic saline solution. It is now understood that such functioning tissues may use sugar which is supplied with the nutrient perfusion liquid. This fact has given an opportunity to compare the sugar-consuming capacity of organs from normal animals and those which have been rendered diabetic. The question to be answered is this: Have the tissues of diabetic individuals lost the capacity to utilize sugar in the usual manner? Hitherto the attempts to answer this question by studying the metabolism of isolated organs have been confined essentially to the perfused heart. The results have been quite uncertain, owing perhaps to wide variations in the stored carbohydrate of the cardiac muscle which could not be estimated in advance. Newer investigations, on surviving intestine, conducted in some of the university laboratories at Budapest[1] have failed to evidence any difference between the intestine of the normal and the diabetic with respect to the utilization of sugar in the way indicated. Even after removal of the pancreas and the initiation of severe glycosuria the isolated tissue can still cause the usual disappearance of sugar from the medium that bathes it. It is important, at this stage of our knowledge of diabetes, not to consider the disappearance of sugar as identical with an actual combustion thereof to its ultimate products of metabolism, carbon dioxid and water. There are too many facts which speak against the retention of a normal capacity to burn up carbohydrates in pancreatic diabetes.[2] For the present we may reconcile the findings by the hypothesis that the katabolism of sugar occurs in stages. The oxidative stage is presumably interfered with by the diseased condition; a preliminary alteration of the sugar molecule may still be possible even in the pathologic organism.[3]

HEALTH CONDITIONS IN THE NAVY

According to the annual report of the Surgeon-General of the Navy,[1] this branch of our national defense, from a medical point of view is prepared to meet at least all peace-time demands. A summary of conditions during the year includes, among other important problems, the outbreak of small-pox on the *Ohio*, which was particularly noted by the lay press at the time. It will be remembered that there were twenty-nine cases of small-pox with five deaths. No cases occurred on the *Vermont*, although her men, examined and vaccinated just before sailing, were exposed in the same manner as those of the *Ohio*. An investigation showed, however, that no vaccination had been done on the *Ohio* for two years before the outbreak, and vaccination of the crew immediately after gave almost 90 per cent. of takes, about what would be expected in an unprotected community. Among 100 recruits received on the *Ohio* shortly before sailing for Europe and vaccinated at that time, not a single case occurred. The report mentions also a slight increase in malaria, which is accounted for by the cases occurring on ships in Mexican waters. The Surgeon-General suggests that the white uniforms of the "bluejackets" be replaced by something of a more serviceable nature, for example, khaki or forestry green. He comments frequently on the need for a hospital ship to accompany each fleet, especially in relation to the operations at Vera Cruz, and the lessons to be gained by their study. This report represents an accurate and informative discussion of the high quality of work in this service.

A NOTE ON THE NON-SPECIFICITY OF CYTOTOXINS

It has been demonstrated that the injection of certain cells into an animal of a foreign species results in the production of cytotoxins in the serum of that animal, but the opinions still differ as to whether or not these cytotoxins are specific for the particular tissue constituting the antigen. Lambert,[2] investigating this question, used tissues growing *in vitro*, which has the advantage over the other methods used by previous investigators of eliminating agglutination, thrombosis and hemorrhages, factors to which Pearce attributed some of the most striking lesions found in organs and tissues after the injection of cytotoxic serums. Rat sarcoma and embryo skin of rats, being suitable for this method, were injected into guinea-pigs, and the serum tested as to its inhibitive action on the growth of these tissues. Lambert found no specificity in the action of cytotoxins. The serum of animals injected with rat sarcoma inhibited the growth of this tissue as well as of the skin of embryo rats and vice versa. The injection of rat blood resulted in the production of substances toxic to these same tissues also, though to a less marked degree. Using the same technic, Lambert obtained similar results with tissues from the embryo chick.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ARKANSAS

Hookworm Infection in Howard County.—In the southern part of Howard County 22 per cent. of 300 people examined are reported infected with hookworm.

Personal.—Dr. Charles W. Garrison, Little Rock, head of the Rockefeller Hookworm Commission work in Arkansas, and assistant secretary of the State Board of Health, has been elected secretary and state health officer to succeed Dr. Frank B. Young, Springdale, who resigned to take the superintendency of the State Hospital for Nervous Diseases. Dr. Garrison has just been appointed collaborating epidemiologist for the government public health service for Arkansas.——Dr. James L. Greene, superintendent of the State Hospital for Nervous Diseases, Little Rock, has resigned. In a statement published by Dr. Greene, it is stated that the cause of his resignation was the enmity of the secretary of the State Charities Board, the reason for this enmity being that Dr. Greene refused to allow a tent to be installed on the hospital premises for the use of a brother-in-law of the secretary of the board, who is suffering from tuberculosis. Resolutions deploring the opposition of members of the State Board of Charities, which resulted in the resignation of Dr. James L. Greene as superintendent of the State Hospital for Nervous Diseases, were adopted by the Social Service Club of Pulaski County and the United Charities of Pulaski County, November 25.

CALIFORNIA

Medical Department Reorganized.—In accordance with regulations, an order was issued November 27, by the adjutant general dividing the medical department of the National Guard of the state into a medical and a hospital corps.

Personal.—Dr. Curtis H. Castle, Merced, a practitioner of the city since 1887, and once congressman from the district, has retired and his practice has been taken over by Dr. Edwin R. Fountain of Portland, Ore.——Dr. Frederic E. Shaw, city commissioner of finance of Sacramento, is reported to be seriously ill.

Mayor Must Be Physician.—Under the new charter amendments which were voted on favorably at Santa Monica, December 2, the city has adopted the commission form of government and the provision is made that the mayor shall serve as health officer. Under the old charter it is provided that the health officer shall be a graduate of a reputable medical college and that he shall practice medicine for at least five years. The first municipal election, under the new form, will be held in December, 1915.

GEORGIA

New Baptist Hospital.—The plans for the new Georgia Baptist Hospital, Atlanta, have been prepared. The new building will cost about $500,000 and will be composed of five units, each containing about 100 beds. One of the units is to be devoted exclusively to the treatment of children.

Personal.—In a $200,000 fire, at Eastman, November 24, the office of Dr. John Cox Wall was burned and a building owned by Dr. John B. Clark was also destroyed.——Dr. James T. Ross, Macon, has been elected chairman of the Bibb County Board of Health.——Dr. James D. Weaver, Eatonton, has been appointed a member of the State Board of Health.——Dr. William C. Thompson, Dublin, has opened the new Thompson Private Sanitarium at Dublin.——Dr. Wyman W. Pilcher, Warrenton, has been appointed official district examiner by the board of trustees of the State Sanatorium.

ILLINOIS

Personal.—Dr. George G. Craig, Jr., has resigned as city physician of Rock Island.——Dr. Cyrus T. Foster, Rock Island, was seriously injured in a collision between his automobile and a trolley car, November 20.

New Hospital.—Dr. James W. Pettit and associates, Ottawa, announce that the Illinois Valley General Hospital will be built on the South Bluff, west of the Ottawa Tent Colony, during the next year, at an expenditure of from $50,000 to $75,000. The first three buildings are to be the administration building which will be flanked on either side by an annex connected by corridors. Especial attention is to be given to the open-air treatment, and all classes of ailments will be treated at the institution.

Chicago

Public Health Exhibit.—A public health exhibit was opened at the City Club, 315 Plymouth Court, November 30, and will remain open until January 16. The exhibits include infant welfare, showing what it adds to the health of the community by the prevention of infant mortality and the limitation of illness; tuberculosis and the life-saving tendency of the education of the people; school hygiene, showing the protection and conservation of the younger generation; food inspection and the method in which food inspection protects against infection, dirty food and harmful adulterants; patent medicines and the good work of the crusade against these harmful products; environmental conditions and the dependence of the people for life and welfare on good surroundings, and that of the Chicago Department of Health and the Municipal Tuberculosis Sanatorium, showing how the administration of public health acts as an instrument for bettering the physical condition and health environment of the community. The greater part of the exhibit is devoted to pictorial charts and maps, graphic representations, etc. The display of the environmental conditions exhibit is one of the most effective: tiny models show a schoolroom with blackboard properly and improperly lighted with good and bad service; proper and improper lighting of a machine in a factory; the living room with four systems of lighting illustrated one after the other; good and bad printed paper, etc. Taken as a whole, the exhibition is creditable but would be more valuable were it less didactic and more pedagogic.

INDIANA

Tuberculosis in Richmond.—A special committee for Earlham College, Richmond, as the result of a sanitary survey, in reference to tuberculosis conditions in Wayne County, ascertained that there are more than 500 cases of tuberculosis in the city of Richmond alone.

Hospital Units Opened.—Two new units of the Indianapolis City Hospital were formally dedicated November 29, the principal address at the ceremony being delivered by Dr. Charles A. L. Reed, Cincinnati. These units have been named the Burdsal Units as they were donated to the city by the late Alfred Burdsal. They have been erected at a cost of $250,000, are three-story structures and provide accommodations for 250 patients. In order to furnish and equip these units, it has been necessary for the city board of health to negotiate a loan of $65,000.

Personal.—Dr. Abner H. Chaffee, Huntington, 86 years of age, was elected treasurer of Huntington County, at the November election and will assume the duties of his office January 1, next. Dr. Chaffee has been practicing medicine in Huntington since 1856, and during the Civil War he served as surgeon to the Seventy-Fifth Indiana Volunteer Infantry.——Dr. Paul E. Bowers, physician in charge of the Indiana State Prison, Michigan City, has delivered a series of lectures on clinical criminology at Valparaiso University.——Dr. Charles P. Cook, New Albany, was operated on for appendicitis at St. Edward's Hospital in that city, November 26.——Dr. Mavity J. Spencer has been appointed police surgeon of Indianapolis, succeeding Dr. Thomas L. Sullivan, Jr., who has been appointed superintendent of the City Hospital.

IOWA

Testimonial Dinner to Mayo.—The Des Moines Pathological Society gave a testimonial dinner to Dr. William J. Mayo, Rochester, Minn., November 28, at which more than

200 physicians were present. In the evening Dr. Mayo delivered an address on "The Septic Factors in the Three Great Plagues."

Personal.—Drs. Joseph C. Powers and Claude F. Osborne, Hampton, announce that they are about to discontinue the practice of medicine in order to prepare themselves for special work in connection with the new Lutheran Hospital. Dr. Osborne is to be surgeon in charge of the new hospital and Dr. Powers is to specialize on diseases of the eye, ear, nose and throat.——Dr. James Alderson, Dubuque, was seriously injured in a collison between his buggy and an automobile, November 21.——Dr. William A. Guild, Des Moines, has arrived in Paris and joined the medical staff of the American Hospital.

Annual Clinic at Medical College.—The physicians of the state were invited to attend the sixth annual clinic of the College of Medicine of the State University of Iowa, Iowa City, December 8 and 9. They were welcomed by the president of the university and on the first day clinics were conducted by Dr. Lee W. Dean of the university, and Dr. Reuben Peterson of the University of Michigan; in the afternoon laboratory demonstrations were given by the following members of the faculty: Drs. Henry J. Prentiss, John T. McClintock, Charles S. Chase and Henry Albert; a clinic on internal medicine was held by Dr. Campbell P. Howard, and after this a visit was paid to the new wing of the University Hospital. On the second morning clinics were given by Drs. Clarence E. Van Epps and John B. Kessler of the university faculty and Dr. Dean D. Lewis, Chicago; and in the afternoon a clinic was given by Dr. Charles S. Grant of the medical faculty, after which an inspection of the university buildings was made.

MINNESOTA

Personal.—Dr. George H. Freeman gave a dinner at the St. Louis Hospital for Inebriates, Willmar, November 24, in honor of Dr. H. W. Hill, executive secretary of the Minnesota Public Health Association. After the dinner an address was given by Dr. Hill before the Commercial Club.——Dr. Gertrude Booker Granger has succeeded Dr. John E. Crewe as whole-time health officer of Rochester.

MISSOURI

Physicians Fill Pulpits.—It is planned to have physicians occupy the pulpits in all the churches of St. Joseph on the Sunday in May next, immediately preceding the meeting of the State Medical Association.

Free Clinic Opened.—A free medical clinic is to be opened in a short time at Admiral Boulevard and Harrison Street, Kansas City. The institution will be a revival of the old Post-Graduate Hospital, which was discontinued some time ago. Dr. C. Lester Hall is president of the new organization.

State to Sell Diphtheria Antitoxin at Low Price.—The State Board of Health has made arrangements for distributing antitoxin at prices ranging from 40 cents for 500 units to $4 for 10,000 units. The city of St. Louis already distributes antitoxin free to persons who cannot afford to buy it, but it is said that many who cannot afford to pay the prices charged by druggists for antitoxin, hesitate to apply for it as paupers. The number of cases of diphtheria reported in St. Louis for five weeks up to November 23 was 546.

New Hospital.—The plans for the Public Hospital bequeathed to St. Joseph by the late Charles W. Noyes have been completed. Mr. Noyes left a bequest of $250,000 to be applied to the erection and maintenance of a hospital to bear his name and the hospital is to be located at Frederick Avenue and Twenty-Fourth Street.——Papers of incorporation of St. Joseph's Hospital, Kansas City, were signed November 30. The building is to cost $500,000 and will be of brick and stone, six stories in height and in the form of an X, and will accommodate about 250 patients.

St. Louis

Leper Found in St. Louis.—The city bacteriologist has diagnosed leprosy in the case of a Greek who came to America in 1912. It is expected that he will be deported by the immigration authorities.

Preventive Medicine Lectures.—A series of lectures on preventive medicine is being given by the Social Service Department of the St. Louis Children's Hospital in the lecture room of that institution on Tuesday afternoons. The series began November 24 and will end January 5.

Free Antitoxin.—Health Commissioner Max C. Starkloff announces that he will apply to the municipal assembly for an appropriation of $3,600 to cover the expense of the free distribution of diphtheria antitoxin by the city. He also states that he will prepare and have presented before the legislature at the January session, a plan providing for the erection of a state bacteriological laboratory in which diphtheria antitoxin will be made and distributed free or at cost.

Medico-Historical Loan Exhibit.—The St. Louis Medical History Club opened a loan exhibit at Jefferson Memorial, December 5. The exhibit is to remain open for two weeks and includes many matters of historical interest, not only to physicians, but to all citizens. Among these are, an autographed letter from Dr. Moses L. Linton in 1847 accepting the professorship in obstetrics and diseases of women in St. Louis University; another from Dr. William Beaumont in 1836, accepting the chair of surgery; other documents of interest are, a petition presented in 1836 appealing for financial assistance for the medical department and an autographed letter from Dr. Daniel Brainard, accepting the chair of anatomy and another autographed letter from William Greenleaf Eliot, accepting as trustee for the medical department; valuable portraits were contributed by Washington University; rare old books have been loaned by Dr. Edward C. Streeter, Boston, and the John Crerar Library, Chicago; and valuable documents have been contributed by Dr. William Pepper, Philadelphia, and the Surgeon-General of the Army.

NORTH CAROLINA

Personal.—Dr. Claude L. Pridgen, Kinston, formerly connected with the State Board of Health, has located in Wilmington.——Dr. Clyde H. Hemphill, Drexel, has returned from New York and will locate in Goldsborough, limiting his practice to diseases of the eye, ear, nose and throat.

Hospital Notes.—Irvin Memorial Hospital, Mount Airy, was formally opened November 12. The building has been erected by Mrs. A. B. Irvin as a memorial to her son, Leonard Irvin. It is a two-story and basement building, fully equipped and has accommodations for thirty patients.——Rex Hospital, Raleigh, held its annual remembrance or donation day, November 11.

NEW JERSEY

Personal.—Dr. Frank H. Carber, Newton, has succeeded Dr. Edward A. McLaine as chief resident physician to the Scranton State Hospital.

Medical Staff Resigns.—The medical staff of All Souls Hospital, Morristown, has resigned in a body to take effect January 1, unless the board of managers make certain changes which the physicians assert are necessary for the proper conduct of the hospital.

Diphtheria.—To November 17, 119 cases of diphtheria had been reported in Jersey City. Dr. Frank H. Edsall, Wilmington, Del., city health superintendent, stated that the city board of health was handicapped by the lack of a well-equipped laboratory and city bacteriologists.

Precautions in Construction of Water Reservoir.—Atlantic City is now building an addition to its storage water reservoir, and in order to protect the water-supply is making a test of its workmen on the job. Dr. Edward Guion, chief of the health department, is making Widal tests in order that no typhoid carrier shall take part in the work on the reservoir.

NEW YORK

New Counsel for Medical Society.—The Medical Society of the County of New York has appointed George W. Whiteside as its counsel. He has been on the staff of the district attorney for seven years.

Personal.—The trustees of the Clifton Springs Sanitarium Company have elected Dr. Malcolm S. Woodbury, superintendent, vice Dr. James G. Mumford, deceased.——Dr. Orie M. Grover, Dunkirk, has been appointed associate physician to the State Reformatory for Women, Bedford Hills.——Dr. Joseph E. Clark has entered on his work as sanitary superintendent for the counties of Oneida and Herkimer.——Dr. Clinton P. McCord, Albany, has been appointed chairman of a committee to organize the open-air-school workers of the state. This movement is closely associated with that for medical examination of schoolchildren and school buildings.

Physical Educators Organize.—At the annual convention of the New York State Teachers' Association in Albany, N. Y., November 23-25, the school medical inspectors and

work in northern Egypt.——Dr. Peter J. Christofferson, Waupaca, had a finger amputated at St. Mary's Hospital, Oshkosh, as the result of an infected wound.——Dr. Henry A. Peters has been elected vice-president, and Drs. Michael R. Wilkinson and Walter S. Wing have been elected directors of the Oconomowoc branch of the Wisconsin Antituberculosis Association.——Dr. Sidney H. Wetzler, Milwaukee, sustained severe burns of the shoulders and chest by the overturning of his automobile, November 7.

Report on Tuberculosis Sanatorium.—The third biennial report of the Wisconsin State Tuberculosis Sanatorium has just been issued. There has been a marked increase in the number of patients treated during the last two years, during which time the capacity of the sanatorium has been increased by the erection of two new patients' cottages and an infirmary, having a combined capacity of fifty-five beds. A new two-story cottage is now being built, which will increase the capacity of the sanatorium to 170 beds. The superintendent recommends a still further increase by the building of another unit of twenty beds for women, and enlarging the infirmary, so as to make a complete capacity for 200 patients. Other improvements are recommended to cost approximately $61,000. ——The new Brown County Tuberculosis Sanatorium has been completed and was opened to receive patients December 1. The construction of the sanatorium came within the appropriation of $22,000. The site and 26 acres surrounding it cost $3,000 and the Brown County board has made an appropriation of $4,000 for interior fittings and furnishings. The institution has twenty bedrooms for patients and two wards.——Kenosha has voted for an appropriation of $20,000 for the erection of a tuberculosis sanatorium for Kenosha County.——Of the $30,000 bond issue for the construction of the Winnebago County Tuberculosis Sanatorium, all but $7,500 has been subscribed.

CANADA

Personal.—Dr. Watson Dykes, Duncan's Station, B. C., has been appointed medical officer of health of South Cowichan, Victoria, B. C.——Drs. John Taylor Fotheringham, James A. Roberts, William B. Hendry and Arthur C. Hendrick are among the Toronto physicians who will go abroad with the second Canadian contingent.——Dr. Albert G. Nicholls, Montreal, McGill University, assistant in pathology and clinical medicine, has been appointed to the chair of pathology in Dalhousie University, Halifax, N. S.

Hospital Reports.—At the seventieth annual meeting of the Montreal Maternity Hospital it was reported that during the last year 1,169 patients were treated as compared with 1,243 the previous year. During the year a nurses' home had been purchased at a cost of $50,000 through a bequest of the late Mr. James Ross. The expenditures and revenue for the year were $40,384 and $41,124, respectively, showing a deficit of $740. The superintendent, Dr. William Bauld, having departed for the war, Dr. C. E. Holbrook has been elected in his stead.

Montreal Vital Statistics for 1913.—After considerable delay the report of the medical officer of health for the year 1913, Montreal, has appeared. In spite of persistent efforts to check infant mortality, the report shows that it increased over 1912 by 1.73 per cent. During 1913 no fewer than 5,732 children died in Montreal under 5 years of age, or 51.65 per cent., of the total mortality. Montreal's infantile mortality rate is one of the highest in the world, being nearly double that of Baltimore, a city approximately of the same size. The deaths due to contagious diseases showed a large increase, as follows: measles, 136; scarlet fever, 184; diphtheria, 173; typhoid, 106; tuberculosis, 897. The deaths in 1912 from these diseases were 14, 80, 77, 94 and 894, respectively.

GENERAL

Correction.—The notice in The Journal of December 5, entitled "Experimental Biologists to Meet," stated erroneously that the name of the federation was the "Southern Experimental Biologists." The correct title of the organization is "The Federation of American Societies for Experimental Biology."

Experimental Biologists to Meet.—The Federation of American Societies for Experimental Biology composed of the American Physiological Society, the American Society of Biological Chemists, the American Society for Pharmacology and Experimental Therapeutics, and the American Society for Experimental Pathology, will hold its next annual meeting at Washington University Medical School, St. Louis, Mo., December 28 to 30.

Red Cross Seals Having Wide Sale.—The Red Cross Seal for 1914 is a reproduction of the jovial Santa Claus. It is having a wide sale. The stamps make a desirable addition to every gift package and represent a thought for those sufferers who should not be overlooked, amid the great disasters occasioned by the war.

Bequests and Donations.—The following bequests and donations have recently been announced:

Home for Destitute Crippled Children, and Mary Thompson Hospital of Chicago for Women and Children, each $100,000 by the will of Alexander A. McKay.

Rockefeller Institute, New York City, $200,000 to be used in research work leading to a cure for cancer, by the will of Henry Rutherford.

University of Pennsylvania, $10,000 for the endowment of a room in the Agnew Pavilion of the hospital connected with that institution, in memory of her husband, Dr. Molton H. Forrest, by the will of Mrs. Emma L. Forrest.

Germantown Hospital, $1,000 by the will of Jenny E. Disston.

Presbyterian Hospital, Philadelphia, $1,000; Philadelphia Society to Prevent Children from Cruelty, $2,000; Philadelphia Society for Organizing Charity, $1,000, by the will of Miss Augusta Tabor.

Nursery and Child's Hospital, New York City, $1,500 by the will of J. Howard Wright.

Eastern District Hospital and Dispensary, Brooklyn, $5,000, by the will of Frederick B. Mollenhauer.

Awarding of Nobel Prizes Postponed.—It is announced from Stockholm that the distribution of the Nobel prizes has been postponed to next fall. After that year, the date of awarding the five prizes is to be changed from December 10 to June or July 1. This will bring the prizes for both 1915 and 1916 into the latter year; they amount to about $38,000 each. As it will be so long before we hear from these prizes again, it may be interesting to recall that to date the prize in medicine has been awarded in turn to Behring, Ross, Finsen, Pawlow, Koch, Ramon y Cajal and Golgi, Laveran, Ehrlich and Metchnikoff, Kocher of Switzerland; Kossel, professor of physiology at Heidelberg; Gullstrand, professor of ophthalmology at Upsala, Sweden; Alexis Carrel and to Richet of Paris. The prize has thus gone to Germany and to France twice each, once each to England, Denmark, Russia, Switzerland, Sweden and America (Carrel), and been divided once between Spain and Italy and once between Germany and France—a truly international list.

Disbanding of Rockefeller Sanitary Commission.—The Rockefeller Sanitary Commission which has had in charge the eradication of hookworm in the southern states under the fund of $1,000,000 granted by John D. Rockefeller in 1909, will disband at the close of the present year. The forces of the commission at that time will be withdrawn from all the states in which they have been working except eight, and the work in these will be taken over by the Rockefeller Foundation, a separate organization. The foundation will close up the work in five of the eight states March 1, 1915, and the remaining three on June 30. Under the foundation there has been created an International Commission on Health which will undertake work for the promotion of health in all parts of the world in cooperation with health departments of all countries, and especially will cooperate in the constructive development of state health forces, not alone with reference to hookworm, but in connection with other health conditions.

Dr. Knopf's Prize Essay as Aid to Tuberculosis Campaign.—Dr. S. A. Knopf informs us that Dr. S. Breitenfeld's Bohemian translation of the seventh American edition of Dr. Knopf's international prize essay, "Tuberculosis as a Disease of the Masses and How to Combat It," has just appeared in book form. The translation appeared first in serial articles in the Bohemian Daily, *New Yorske Listy*. On account of there being many large Bohemian colonies throughout the United States, the appearance of the translation is welcomed by all who are interested in the tuberculosis problem, and particularly by physicians practicing in Bohemian colonies. The latest American edition of this essay is now also being translated into Spanish by Dr. Jesus E. Monjaras of Mexico City. The translation of the essay into various European and Asiatic languages since its original appearance in Germany some ten years ago, speaks well for the universal interest now taken in the antituberculosis campaign throughout the civilized world.

FOREIGN

Death of Spanish Physician Aviator.—Dr. Cortijo, who recently lost his life in an accident to his aeroplane, was a medical officer in the Spanish army and member of the aviation corps.

Malaria in Italy.—The report of the Italian Red Cross for 1912-1913 states that six units were sent into new territory and four into the Pontine marshes and one to the Campo Soriano. The number of cases in the district near Rome was only 5.1 per cent. and in the Pontine marshes 4.9 per cent., the lowest figures yet reached. Dr. P. Postempski is the medical inspector in chief for the service.

Typhoid at Barcelona.—Our Spanish exchange, the *Siglo Medico* of November 7, states that the severest epidemic of typhoid Barcelona has ever known is prevailing there now, although the mortality is not very high. One daily estimates that there have been 30,000 cases, and a communication from a local physician places the number as much above 15,000, while the authorities have over 5,000 registered cases. The hotels were crowded with refugees from the war zone, but the city is now deserted by all of them who can leave. Notwithstanding vigorous sanitary measures the epidemic shows no signs of abating, 400 cases a day being still reported.

Hookworm in Iquitos, Peru.—Dr. George B. Converse, U. S. Public Health Service, has returned to San Francisco from Iquitos, Peru, where, at the request of the Peruvian government, he has spent almost three years investigating the death-rate of about 50 per 1,000 and instituting sanitary reforms. Yellow fever and hookworm were the diseases responsible for the greatest amount of the mortality and morbidity. His work was hampered by lack of hospital facilities. Before he left, however, he had succeeded in reducing the death-rate to 21 per 1,000 and had established a well-equipped clinic.

WAR NOTES

Lack of Medical Supplies in Servia.—Servian hospitals are said to have run short of anesthetics early in November. There is also a shortage of surgical instruments in the field hospitals.

Queen Visits War Hospital.—Queen Mary of England visited the American Hospital at Paignton, England, November 29, and commended most highly the administration of the institution.

Graduating Class Volunteers as a Body.—Every member of the graduating class of the medical school connected with Dalhousie University, Halifax, N. S., has volunteered for service in the European war.

More Surgeons Needed for Russians.—In response to an appeal from Russia for surgeons, the American Red Cross has arranged to send two more surgeons to reenforce the units already on duty with the Russian forces.

Anesthetics Still Needed.—The British War Relief Association, Washington, has sent five cases of chloroform to the American ambassador in Paris, and letters from France appeal for still further contributions for anesthetics.

Scientist Taken Prisoner.—Dr. Albert Calmette, director of the Pasteur Institution at Lille, a staff officer in the French medical service, who has been missing for some time, is now said to be a prisoner of war at Munster, Westphalia.

Decorations for German Medical Officers.—The *Münchener med. Wochenschrift,* November 10, states that the iron cross has been conferred on 920 physicians to date. The iron cross of the first class was awarded during the Franco-Prussian War only to Langenbeck, Wilms and Bardeleben.

Change from Quarterly to Monthly.—On account of the rapid increase of membership of the American Red Cross and the broadening of its field of usefulness, the *American Red Cross Magazine* will hereafter be issued monthly instead of quarterly, beginning with the January number.

Medical Officers in German Army.—The surgeons with the German army rank as officers and are entitled to wear sidearms. The authorities have also recently announced that civilian medical men serving in the field are entitled to a pension if incapacitated by wounds or sickness and the family to a pension in case of death.

Dissolution of the International Public Health Office at Constantinople.—Our German exchanges state that the government of Turkey has suspended the operations of the *Internationale Sanitätsrat* and invited the members to join the medical corps of the Turkish army. The International Health Office was mainly engaged in supervising the pilgrimages to Mecca and preventing the importation of epidemic disease into Europe.

War News In Germany.—Germany seems to be in part shut off from communication with France and England. According to the *Deutsche med. Wochenschrift* of November 12, nothing has been heard from its London correspondent since the war began, and its Paris correspondent is at work in an ambulance in Germany. It reproduces entire the long Paris Letter in The Journal of September 19, and the London Letter in the issue of September 26. War makes strange arrangements necessary and it is interesting to find a German periodical printing from an American publication news of English and French activities.

Clothing Gifts for Europe.—The American National Red Cross requests that all gifts of clothing, and hospital garments and supplies for the distressed people of Europe, be forwarded freight prepaid, to the American Red Cross, Bush Terminal, Thirty-Ninth Street and Second Avenue, South Brooklyn, N. Y., and that the Bureau of Medical Service, Washington, be notified of the number of suit cases, packages, etc., with approximate contents and day on which they were forwarded. Bills of lading should be sent to the address at South Brooklyn. Second-hand clothing is not acceptable, but new clothing, hospital garments and hospital supplies, such as sheets, pillow cases, towels, etc., are always useful.

Behring and Metchnikoff.—Metchnikoff will be 70 years old next year, and a *Festschrift* for him has been in preparation at Paris for this anniversary. Behring had intended to contribute an article to it, but the breaking out of the war prevented his article reaching the publishers on time, that is, before September 1. He now publicly announces (November 12) that he hopes "before the anniversary in question, next May, to manifest in some other way my respect and unwavering friendly sentiments for Metchnikoff on the occasion of his seventieth birthday." Metchnikoff is a Russian, and has devoted the last twenty-six years of his life to research at the Pasteur Institute at Paris. His discovery of the phagocyte was made before he went to Paris. Like Pasteur, he never completed the medical course.

LONDON LETTER

London, Nov. 15, 1914.

The Kind of Nurses Wanted at the Front

Sir John French has made it known that no one is wanted near the fighting line except fighting men and fully trained men and women pledged to devote themselves to the duty of healing and nursing the wounded for the duration of the war. The amateur nurse is of no use there. He very wisely adds that women who want to enlist in the great army of nurses that will be needed before the war is finished should be learning their profession at home till their services at the front are asked for. "The standard of British hospitals here," he is reported by the special correspondent of the *Daily Call* as saying, "is so high and admittedly so far above that of all the rest, that women chosen to serve with British comrades on this side of the channel should lack no qualification she can with diligent effort acquire. The thoughtful skill of a few seconds may save a life. There is never a moment to be lost in these crowded nights when the lives of a hundred poor victims hang by a thread and the watchful zeal of a patient, resourceful woman alone can avail." Sir John French concludes with the warning that it is time that every woman in Britain who has intelligence and the requisite earnestness should begin, if she has not yet done so, to learn the elements of nursing, if only "first aid," for the war must be long and there will be many gaps to fill.

Aid for Our Belgian Colleagues

Physicians have suffered like the rest of the Belgians, and those who have survived have been completely ruined. According to Professor Jacobs of the University of Brussels, who is now in this country, some have had to work as navvies in order to obtain a few pence. Others have not seen bed for a fortnight and have lived exclusively on potatoes. Some have had a bunch of straw and lie on the ground, and they and their children are dressed in rags. A professor of a university was bereft of everything and in dire want of a bed. Another was seen wandering haggard over the countryside searching in vain for his family. Some have been taken as hostages; others have been shot and their widows and orphans left destitute. Of the 4,800 physicians of Belgium, 1,000 are absolutely destitute and most of the remainder are suffering cruelly. In my last letter I announced the formation of a committee of the leaders of the medical profession for the aid of our Belgian colleagues. It has been decided to dispatch to Belgium packets of medical and pharmaceutical material which will be received by the American ambassador.

The committee appeals to the medical and pharmaceutical professions in this country for funds to enable their Belgian colleagues to begin work as soon as military circumstances permit. It also asks for surgical instruments, not necessarily of the latest pattern. The following are especially required: scissors, dressing and artery forceps, syringes and midwifery forceps. Further, money is wanted to help the refugee physicians and pharmacists in this country who have nothing left in the world. It is proposed to associate our work with corresponding efforts in the United States and other countries. Subscriptions may be sent to Dr. H. A. Des Voeux, 14 Buckingham Gate, London, S. W. Many physicians in this country are offering hospitality to their colleagues, and the British Medical Association has given the use of the office as a clearing house for collecting their names through the *British Medical Journal.*

Sanatogen and the War

The government has prohibited all trading with the enemy and the carrying on of any business in this country which is the property of enemies resident in Germany. This has proved a blow to one of the most successful of the fraudulent nostrums of the day, Sanatogen. As it is a German preparation it can no longer be sold. An attempt has been made to evade this prohibition. An application was made to the Home Secretary for permission to convert the business into an English limited company. He refused to sanction such an arrangement and directed that steps should be taken to prevent any profits being transmitted to the proprietor during the war. A British company has now been formed for the sale of a product termed "Sanaphos," which is wholly British owned and British made. It is being widely advertised in the daily press as displacing Sanatogen. The public is informed that "Britishers and their allies are now independent of Sanatogen." "All patriotic men and women," it is said, "will welcome an opportunity of obtaining a British product instead of benefiting an alien enemy by taking a German-owned preparation." "Sanaphos is an all-British preparation, and the fact that the company producing it is under the chairmanship of Sir William Taylor, K.C.B., the late Surgeon-General of H. M. forces, and that the article is produced under the direct supervision of a distinguished analyst, are sufficient guarantees of its efficacy and superiority. Sanaphos has its basis in English milk, and, unlike Sanatogen and its imitations it retains all the active enzymes of milk, and is not a mere dried casein preparation. The extravagant prices at which Sanatogen was sold not only enriched its German owner, but prevented its use among those who could not afford such prices. Those who see, in themselves or in members of their families, the results of the new cares, new duties and general strain of war-time, involving nervous or mental depression or physical exhaustion should take steps at once to procure a supply of Sanaphos to be used as an addition to ordinary diet." Evidently the same old game. The Germans have no monopoly in fraudulent claims.

PARIS LETTER

Paris, Nov. 12, 1914.

The Waterproofing of Military Clothing

Ever since the war of 1870 chemists have proposed a method of waterproofing military clothing by the use of watery solutions of aluminum acetate. The objection has been raised that the results are not sufficiently permanent, for the waterproofing disappears under repeated friction, as by the straps of the haversack, etc. Moreover, if the metal braid and buttons of the uniform are not detached before the treatment, they will be covered with verdigris; besides the procedure spoils the looks of the clothing, which requires a long time to dry. M. G. A. LeRoy has reported to the Académie des sciences a process of waterproofing which seems free from these objections. It is based on a very light impregnation of the fibers of the cloth with anhydrous wool fat (adeps lanae anhydrosus) dissolved and diluted in a neutral and volatile anhydrous vehicle. Wool fat is first liquefied by means of a little chloroform, carbon bisulphid or carbon tetrachlorid and then diluted and dissolved in automobile gasoline or the benzin employed by cleaners. The proportions employed are from 5 to 10 parts of wool fat and from 90 to 95 of solvent. The whole uniform, with its braid and buttons, is immersed in the liquid for a few minutes, then wrung out and placed in the air to dry. The fat, fixed in the fibers and pores of the cloth on the evaporation of the solvent, cannot be removed by friction like the particles of the aluminum acetate. The waterproofing is perfect and the appearance of the cloth, its porosity, its color and its elasticity are not modified. An important hygienic advantage is that the cloth remains permeable to air and perspiration.

Treatment of Gangrenous Military Wounds

Apropos of the paper by Professor Quénu on the treatment of gangrenous military wounds by opening up and sterilizing with hot air (The Journal, Nov. 28, 1914, p. 1967), Dr. Paul Thiéry, surgeon of the hospitals of Paris and agrégé of the Faculté de médecine, recommends the use, in serious cases of septicemic military wounds, of hypodermic injections of from 0.01 to 0.02 gm. of pilocarpin repeated daily. The profuse perspiration caused by the pilocarpin, together with the ingestion of abundant liquid, sometimes even with intravenous injection of a physiologic solution of sodium chlorid, produces a veritable lavage of the blood, which is less depressing than bleeding and which relieves the blood of toxins while preserving the blood corpuscles. This procedure is capable of giving good results even in desperate cases. Thiéry insists, moreover, on the necessity of return to the most energetic measures of the old antiseptic surgery (concentrated solutions of zinc chlorid).

BERLIN LETTER

Berlin, Nov. 3, 1914.

The War

The effort of the head of the army medical service to care for the enormous number of wounded as quickly and as well as possible has caused the enrolment of a constantly increasing number of physicians in the army. Physicians who belong to the military reserves have already been employed. Physicians who, for physical reasons, have never undergone military service have also been enlisted, in some cases at the seat of war and to a greater extent in the hospitals in their home towns. In this way also some relief has come to many physicians whose practice has been diminished through the departure for the seat of war of a large number of men, among whom are workmen who are exposed to industrial diseases and accidents. This circumstance alone does not explain the fact that many gynecologists and pediatrists complain of a striking lack of professional work; other causes must be found. In the first place, the war may be considered as occupying our minds so completely that in many cases it has crowded out complaints which affect the welfare of men in normal times and cause them to seek medical aid. This applies, particularly, to the large mass of nervous complaints of women but also to the milder organic diseases, which lose importance in comparison with the great tension and the not inconsiderable care for the welfare of the fatherland and for relatives in the field. In addition, there is doubtless an economic factor, the necessity to limit expenses as much as possible in view of the lessened income. Even in times of peace, physicians are well acquainted with the fact that avoidance of a physician's fee is regarded as preferable to the restriction of food or similar demands. Finally, there has been no epidemic of importance. While in autumn, we are often enough sufferers from measles, scarlet fever, typhoid, etc., these diseases so far have not appeared in any notably greater degree than in the summer months.

Epidemic Diseases

From the point of view of the public health and the psychic and economic life of our city, the absence of epidemics is most gratifying. Their importation, so liable to occur in war, has not taken place. In this respect we are better off than our ally, Austria-Hungary. There an invasion of cholera has occurred, both from the Servian and the Russian troops; in Hungary and Galicia several hundred cases have been observed. In view of the nearness of the two allied countries, of course, the danger for us of seeing the unbidden guest on our boundaries is not slight. But we may hope that the excellent organization of our sanitary service will be able even under the present serious condition to protect our boundaries, and even if a transmission of the disease should occur, to restrict it to sporadic cases. Although the war has already lasted three months, and the conditions of the weather in the last month have not been favorable, other war pestilences which, in former times, have demanded an enormous number of victims, so far have not occurred to an extent worth mentioning. Already in the East, where we have come into such unpleasant contact with the permanent epidemic foci of Russia, the number of typhoid cases observed is so small that it has scarcely exceeded the first hundred, and in the same manner dysentery is confined to very moderate limits. It is noticeable, moreover, that affections of the intestine accompanied by bloody diarrhea have been observed in which the germ of dysentery could not be demonstrated. In the West, the prevalence of typhoid seems to be somewhat more marked, but there also are apparently only a few hundred cases, which is also true of dysentery. Whether the typhoid preventive vaccination, which has been carried out to a great extent in our various armies, is of any essential importance in causing this restriction of typhoid, cannot at present be decisively determined. In this respect, a more definite idea will be obtained by comparison of the typhoid cases which occur without prophylactic inoculation with those which occur in spite of it. Small-pox has not hitherto been observed. This fact is not remarkable, for our army, even in time of peace, has been free from small-pox and now all troops have been vaccinated previous to going to the front. Moreover, among the French, vaccination has been better carried out than in the war of 1870-1871; at that time, as is well known, both the civil population and also the army was attacked with small-pox and many deaths occurred in the army. Also among the French prisoners of war who were confined in Germany, small-pox prevailed at that time to a considerable degree, and the disease was communicated by them to the German civil population.

The Number of Wounded

It is not generally known to what extent the weather has had an influence on the origin of colds, especially on pneumonia. So far as I know, large numbers of these cases have not been observed in the hospitals. An estimate of the number of wounded can be made from Berlin alone, where, in the hospitals and in the private clinics, casinos, restaurants and other buildings devoted to hospital purposes, more than 12,000 beds for the wounded have been provided. The arrangements are in general, as I have been able, personally, to convince myself, of the model kind. Even the improvised hospitals have quickly met the highest demands for comfort and for the care of the sick. Roentgen apparatus is generally in use with good operating rooms, individual rooms, etc. The course of wounds and diseases remains in general very favorable, and even severe wounds heal in part without disturbance of function, and the convalescents are anxious to return to the front as soon as possible. In this way, place is found for fresh cases. As I learn, 5,073 men have been already dismissed from one of the Berlin convalescent stations since its institution, August 30. Of these, 1,899 (37.5 per cent.) went immediately to the front, 2,854 (56 per cent.) were transferred to the reserve department of the army and only 322 (6.5 per cent.) were incapable of service. As the reserve department of the army naturally very soon dismisses to the front the majority of those sent to it, and as the figures quoted refer only to one of the many stations for those slightly wounded, an approximate estimate may be made of the enormous number of wounded and sick soldiers who have recovered and who are now fighting again in the ranks of the army. The same is true of the hospitals of other countries, and thus it is possible for the stream of transports for the wounded to pass without disturbance and without stopping, from the field of battle to their homes where, it is easy to understand, the patients are better taken care of than in the field hospitals. It is also evident that in this way the origin and spread of diseases is limited. Recovery also is favored by the better provisions for nursing in the home towns. Several head surgeons of the hospitals have described to me how the wounded who were brought here directly from the field of battle and who came here exhausted, not only as the result of their wounds but also from the severe strain of the battle, took a new appearance of life after twenty-four hours of rest in a good bed and careful feeding and were scarcely recognizable. Everything that human care and gratitude is capable of is done for the restoration of the wounded. It is touching and inspiring to see how rich and poor, high and low, compete to show their love for those who have given their blood for the fatherland. In the hospitals, concerts are given by noted artists, declamations, humorous performances and, of course, divine service—everything that will have a favorable psychic influence on the sick. If they are able to go they are taken to the theater, to the zoological gardens and to other places of recreation. One might almost get the impression that the wounded were being coddled and that they would feel so much the more severely the contrast between the agreeable home land and the rough war to which they return. However, this objection is of little consequence in comparison with the strengthening of the spirit which must be accomplished by the activity in the general undertaking. That this activity for our soldiers is expressed also by the amount expended for presents is natural.

Marriages

Kenna Jackson, M.D., Richwood, W. Va., to Miss Neva Bernice McMillion of Love Ridge, W. Va., at Washington, D. C., November 4.

Mary Catherine Couch, M.D., Chicago, and Mr. Tomas T. Mora of Fajardo, P. R., at Rio Piedras, P. R., November 19.

Lieut. George Corwin Beach, M. R. C., U. S. A., to Miss Jessie Spencer of National Soldiers Home, Va., November 16.

Rafe Chester Chaffin, M.D., Los Angeles, Cal., to Miss Marion Quinn of Ottawa, Ont., at Los Angeles, November 17.

Walter Chafey Moodie, M.D., Newcastle, Neb., to Mrs. Mabel Odom of Walthill, Neb., at Macy, Neb., November 7.

Colonel James Edson Miller, M.D., Brooklyn, N. Y., to Miss Lucy Regina Berry of New York City, November 14.

Harry Leslie Franklin Locke, M.D., to Miss Katherine Elizabeth Entress, both of Hartford, Conn., November 11.

Thomas Francis Henry, M.D., Salem, Mass., to Miss Jennie Frances Moore of Woburn, Mass., November 11.

Charles Patton Blair, M.D., Monmouth, Ill., to Miss Lena Blanche Wilson of Des Moines, Ia., October 10.

Ernest Henry Gruening, M.D., Boston, to Miss Dorothy Elizabeth Smith of Norwood, Mass., November 19.

William George Patton, M.D., to Miss Emma Elizabeth Giessing, both of Farmington, Mo., November 17.

Charles Hartwell Cocke, M.D., Asheville, N. C., to Miss Amy Grace Plank of Philadelphia, November 12.

Robert Vincent Williams, M.D., to Miss Matilda Reinhart, both of College Point, N. Y., November 19.

Lieut. Chester R. Haig, M. C., U. S. A., to Miss Hilda Morse of Merchantsville, N. J., November 11.

Charles P. Renner, M.D., to Miss Gertrude Harst, both of Belleville, Ill., at St. Louis, November 17.

Herbert C. Blake, M.D., Baltimore, to Miss Helen Niely of Paradise, Catonsville, Md., November 14.

Claude Carlisle Caylor, M.D., to Miss Alice Donnelly, both of Washington, D. C., November 18.

Walter Wilson Griffin, M.D., Manhattan, to Miss Mattie Fox Vaughan of Brooklyn, November 16.

Henry Gifford Bull, M.D., Ithaca, N. Y., to Helen Dudley, M.D., of Brooklyn, November 21.

Clyde Earl Wilson, M.D., to Miss Caroline Grace Geyman, both of Blue Earth, Minn., November 12.

Robert Emmett Flannery, M.D., to Miss Mary Kearns Black, both of Chicago, November 11.

Deaths

Charles Wood McMurtry, M.D. Harvard Medical School, 1897; a Fellow of the American Medical Association; a member of the New York Academy of Medicine and many dermatological societies; instructor in dermatology in the College of Physicians and Surgeons in the City of New York; assistant dermatologist to the Vanderbilt Clinic and St. Luke's Hospital, New York City; for eleven years connected with the Dermatological Clinic at Breslau, Germany; died at his home in New York City, November 26, after an operation for appendicitis, aged 42.

Henry X. Bonebrake, M.D. Bellevue Hospital Medical College, 1865; a Fellow of the American Medical Association and formerly president of the Medical Society of Franklin County; for many years in charge of the State Tuberculosis Dispensary, Chambersburg, Pa.; visiting physician to the Chambersburg Hospital and Franklin County Almshouse, and county inspector for the State Department of Health; died November 22, at the State Sanatorium, Markleton, Pa., from chronic nephritis and arteriosclerosis, aged 71.

Sherbourne William Dougherty, M.D. University of Pennsylvania, Philadelphia, 1894; a Fellow of the American Medical Association; instructor in physical diagnosis in his Alma Mater and chief of the medical clinic at the German Hospital, Philadelphia; later assistant physician at the Methodist Hospital and physician to the Society for the Prevention of Cruelty to Children; died at the home of his sister in Philadelphia, November 23, aged 45.

William Wightman Mangum, M.D. Atlanta (Ga.) Medical College, 1893; a member of the Medical Association of Georgia; and formerly president of the Butler County, Ala., and Floyd County, Ga., medical societies; local surgeon at Rome, Ga., for the Nashville, Chattanooga and St. Louis Railway; medical director of the Cherokee Life Insurance Company; died in the Grady Hospital, Atlanta, Ga., November 18, aged 47.

Clark M. Galloway, M.D. Medical College of Ohio, Cincinnati, 1877; of Xenia, Ohio; a member of the Ohio State Medical Association; chief of staff of the Old Sailors' and Soldiers' Home, Xenia; a veteran of the Civil War, and medical director for the Department of Ohio of the Grand Army of the Republic in 1890-91; died at the home of his brother in Dayton, November 20, aged 70.

James W. Gaines, M.D. Medical College of Ohio, Cincinnati, 1886; a Fellow of the American Medical Association; professor of otology in the Medical Department of the University of Kansas; laryngologist and rhinologist to St. Joseph's Hospital, Kansas City, Mo., and consultant to St. Margaret's Hospital, Kansas City, Kan.; died at his home in Kansas City, Mo., November 22, aged 51.

William Henry Baker, M.D. Harvard Medical School, 1872; founder of the Gynecological School for Advanced Students at Harvard; founder of the Free Hospital for Women, Brookline, Mass., and surgeon emeritus of that institution; a member of the Massachusetts Medical Society; died at his home in Waltham, November 26, from heart disease, aged 69. (Bu)

Evan Cameron, M.D. Medical School of Maine, Brunswick, 1869; Bellevue Hospital Medical College, 1872; of Elyria, Ohio; a Fellow of the American Medical Association; founder and formerly president and treasurer of the Lorain County Medical Society and coroner of Lorain County; died in the Memorial Hospital, Elyria, October 8, from pneumonia, aged 65.

James Leeworthy Camp, M.D. Rush Medical College, 1879; a member of the Minnesota State Medical Association and of the Advisory Commission of the Minnesota State Sanatorium for Tuberculosis, Walker; for thirty years a resident of Brainerd, Minn.; was found dead in his bed in Brainerd, November 22, from heart disease, aged 59.

Harold Willis Hartwell, M.D. University of Michigan, Ann Arbor, 1883; New York Homeopathic Medical College, New York City, 1884; died at his home in St. Louis, November 17, from heart disease, aged 56.

Philip G. Creveling, M.D. Pennsylvania Medical College, Gettysburg, 1858; for more than half a century a practitioner of New Jersey; died at the home of his daughter in Broadway, N. J., November 5, aged 80.

Andrew S. Low (license, years of practice, Pennsylvania, 1888); for forty-three years a practitioner of Pennsylvania and a veteran of the Civil War; died at his home in Philadelphia, November 9, aged 77.

J. M. Pounds, a pioneer practitioner of Hays County, Texas, and a veteran of the Mexican and Civil wars; died at his home near Dripping Springs, Texas, October 20, from arteriosclerosis, aged 87.

Andrew J. Jackson, M.D. University of Buffalo, N. Y., 1873; a Fellow of the American Medical Association; died at his home in Matawan, N. J., November 17, from pneumonia, aged 72.

Thomas W. Botkin (license, Indiana, 1897) for forty-five years a practitioner of Farmland, Ind.; died at the home of his son in that place, November 19, from cerebral hemorrhage, aged 70.

James C. McIntosh, M.D. University of Pennsylvania, Philadelphia, 1846; one of the oldest practitioners of Knoxville, Tenn.; died at the home of his son in that city, November 8, aged 89.

J. H. Sensabaugh (license, Tennessee, 1889); a Confederate veteran and formerly a clergyman of the Methodist Episcopal Church; died at his home in Knoxville, November 8, aged 69.

Erving Asa Libbey, M.D. Medical School of Maine, Portland, 1897; a member of the Providence (R. I.) Medical Society; died at his home in Cranston, R. I., October 7, aged 39.

O. M. Humston, M.D. Louisville (Ky.) Medical College, 1874; a member of the Kentucky State Medical Association; died at his home in Campbellsburg, Ky., November 14, aged 63.

Samuel P. Brundige, M.D. Medical College of Ohio, Cincinnati, 1872; a veteran of the Civil War; died at his home in Marion, Ind., November 10, from cerebral hemorrhage, aged 77.

Isaac N. Smith, M.D. Medical College of Ohio, Cincinnati, 1874; of Greenfield, Ohio; died at the Good Samaritan Hospital, Cincinnati, November 6, from carcinoma, aged 67.

Charles S. Morris (license, Colorado, ten years practice, 1900); formerly of Snyder and Julesburg, Colo.; died in his home in Brush, November 11, from pneumonia, aged 70.

Charles Eugene Harvey, M.D. Bellevue Hospital Medical College, 1889; Medical School of Maine, Brunswick, 1889; died at his home in Bristol, Vt., September 26, aged 51.

Alexander McCully, M.D. Washington University, St. Louis, 1902; formerly of Wellsville, Mo.; was found dead at his home in Nooksack, Wash., October 27, aged 36.

Carl Edward Maaser, M.D. University of Iowa, Iowa City, 1914; of Waverly, Ia.; died in the General Hospital, Montreal, Que., October 18, from septicemia, aged 26.

Thomas W. Hightower, M.D. Southern College of Medicine and Surgery, Atlanta, Ga., 1914; died at his home in Atlanta, August 18, from pneumonia, aged 32.

Daniel Kingsbury, M.D. Metropolitan Medical College, New York City, 1852; died at his home in Glastonbury, Conn., November 16, from senile debility, aged 86.

Pierce Tyrrell, M.D. Eclectic Medical Institute, Cincinnati, 1866; one of the oldest practitioners of Illinois; died at his home in Elgin, November 19, aged 85.

Robert Emmett Foley, M.D. Bennett Medical College, Chicago, 1880; died at his home in Stockton, Cal., October 28, from disease of the heart and liver.

Allen J. Alston, M.D. Howard University, Washington, D. C., 1890; a colored practitioner of Boynton, Okla.; died at his home in that place in August.

Joseph R. Blackford, M.D. University of Tennessee, Nashville, 1895; died at his home in Linton, Ky., November 4, from cerebral hemorrhage, aged 42.

Charles M. Eaton, M.D. Medical College of Indiana, Indianapolis, 1878; died at his home in Robinson, Ill., September 10, from nephritis, aged 68.

Joseph Lowman Campbell, M.D. Western Pennsylvania Medical College, Pittsburgh, 1889; died at his home in Chicora, Pa., November 9, aged 53.

Thomas Rud Wingo, M.D. Jefferson Medical College, 1860; a Confederate veteran; died at his home near Trezevant, Tenn., November 5, aged 88.

Alonzo William Morelen, M.D. Medical School of Maine, Brunswick, 1902; of Cherryfield, Maine; died in Bangor, Maine, October 11, aged 43.

B. Blake Minor, Jr., M.D. McDowell Medical College, St. Louis, 1866; died at his home in Beaumont, Texas, November 1, from cerebral hemorrhage.

Thomas M. Howard, M.D. Louisville (Ky.) Medical College, 1878; died at his home in Boonville, Ind., November 17, from asthma, aged 68.

Milton Covert (license, Ohio, 1896) for twenty-six years a practitioner of Youngstown, Ohio; died at his home, November 15, aged 61.

James William Bryant, M.D. University of Louisville, Ky., 1873; died at his home in Lyerly, Ga., November 10, from tuberculosis, aged 54.

Amos H. Farrish, M.D. Atlanta (Ga.) College of Physicians and Surgeons, 1901; died at his home in Perry, Ark., November 3, aged 45.

Thomas N. Moxon, M.D. Central Medical College, St. Joseph, Mo., 1896; died at his home in Salida, Colo., November 8, aged 50.

Elmer Dallus Snyder, M.D. Louisville (Ky.) Medical College, 1892; died at his home in Radnor, Ind., September 5, aged 49.

Joseph Arrington Blick, M.D. Jefferson Medical College, 1859; died at his home in Petersburg, Va., November 3, aged 78.

John S. Wilson (license, Missouri, 1883); died at his home in Deepwater, Mo., November 8, aged 66.

Jason Roberts, M.D. Medical College of Ohio, Cincinnati, 1865; died at his home in Osceola, Ia., November 5, aged 77.

James Leslie, L.R.C.S. Edin., 1858; died at his home in Hamilton, Ont., October 18, aged 82.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

THE EDITORIAL DR. JEKYLL AND THE ADVERTISING MR. HYDE

While The Journal has devoted more space to criticizing the lack of consistency between the editorial and advertising departments as it appears in medical journals, its existence in the lay press has not been overlooked. Franklin P. Adams who conducts a "colyum"—"The Conning Tower"—in the New York *Tribune* thus sums up the case as it applies to newspapers:

The Double Standard

"Important is the nation's health
Naught is the question of the shekel.
Ill fares the land that worships wealth!"
Says Editorial Dr. Jekyll.
"Do you get up with pains or cricks?
Do you have stitches in the side?
BUY DR. KILLMAN'S VI-TE-LIX!"
Says Advertising Mr. Hyde.

"Down with the greedy grafters who
The land's escutcheon do bespeckle!
Three cheers for the Red, White and Blue!"
Says *Editorial* Dr. Jekyll.
"Does zero weather give you chills?
Insomnia leave you weary-eyed?
BUY PHAKEM'S PHONY PURPLE PILLS!"
Says Advertising Mr. Hyde.

"Better than gold an honest name."
"Be true, and let the envious heckle."
"Be fair, whoever wins the game,"
Says Editorial Dr. Jekyll.
"Lost energy? Ambition? Calm?
GET DR. FIERCE'S GILDED GUIDE
REMEMBER BIDDY BUNKEM'S BALM!"
Says Advertising Mr. Hyde.

ARTICLES REFUSED RECOGNITION

Reports of the Council on Pharmacy and Chemistry

[Below appear abstracts of the Council's action on articles refused recognition which were not deemed of sufficient importance to require a lengthy report. Articles with the titles starred will be printed in full in the Reports of the Council on Pharmacy and Chemistry for 1914. A reprint of any of these unabridged reports will be sent on receipt of a two cent stamp. Previous instalments of abstracts appeared in The Journal, November 14 and November 21.]

Alborum

The Whitehouse Chemical Company, Inc., Lynchburg, Va., gives the ingredients of Alborum (without specifying the proportions), as boric acid, alum, phenol and oil of peppermint, and its properties as antiseptic, germicide, deodorant, astringent, hemostatic and prophylactic. The manufacturers recommend it:

> ". . . In the treatment of Leucorrhoea, Pruritus, Vaginal Catarrh, Gonorrhoea, Inflammation of the Genital Organs, and the various Diseases of the Vagina and Uterus . . . In burns, irritable painful lacerations, and in infected wounds, Alborum is often very serviceable."

Such recommendations for its use can only result in injury to the public health. The preparation lacks originality and is unscientific; its exploitation for the purposes suggested in the advertising matter submitted is contrary alike to the best interests of the public and to scientific medicine. The Council, therefore, held Alborum to be ineligible for inclusion with either New and Nonofficial Remedies or the appendix.

The Council's action was transmitted to the Whitehouse Chemical Co. for comment. Instead of objecting to the report, the company asked the Council to "cancel" the application for the examination of the product. Believing that the medical profession is entitled to the facts in the case the Council directed publication of this report.

Betul-ol *

Betul-ol (E. Fougera and Co., New York) is a methyl salicylate preparation advertised to physicians (and indirectly to the public) as an external analgesic and antirheumatic. The statements regarding its composition are vague, misleading and, as shown by examination in the Chemical Laboratory of the American Medical Association, untrue. The therapeutic claims are based on discarded theories. Although the alleged superiority of natural over synthetic salicylates has been disproved, physicians are urged to use Betul-ol because it contains, or is alleged to contain, a natural salicylate. Another discarded theory is pressed into service in the claim that the chloral in the mixture will be absorbed and converted into chloroform in the blood. The recommendations for the use of Betul-ol in rheumatism are likely to lead the public to the self-treatment of rheumatism. In view of the serious complications and sequelæ of rheumatic fever this recommendation is utterly unjustifiable and a danger to public health—even if the external application of this mixture in uncertain doses were as effective as a proper internal use of salicylates—a theory contrary to experience and unsupported by adequate evidence.

Cystogen, Cystogen Aperient and Cystogen-Lithia*

Cystogen is the therapeutically suggestive name applied to hexamethylenamin by the Cystogen Chemical Company. While investigation has shown that hexamethylenamin yields formaldehyd only in the presence of an acid and consequently can produce an antiseptic effect only in the gastric juice and in the urine, it is claimed that Cystogen is an "intestinal antiseptic" and that it "bears its disinfectant and antitoxic qualities into well-nigh every important bodily cavity."

As the sale of a simple drug even with the aid of the most extravagant claims probably did not offer sufficient opportunity for an extensive proprietary propaganda, the Cystogen Company has put out two other preparations, Cystogen Aperient and Cystogen-Lithia, and finds it an easy matter by means of extravagant claims, unwarranted assertions and pseudo-scientific arguments to recommend the use of one or another, or often all three, in a well-nigh endless number of diseases.

As the continued patronage of the medical profession cannot be relied on for proprietaries of this sort, the Cystogen Chemical Company takes good care that every Cystogen prescription is likely to spread the Cystogen gospel among the people. The Council has directed publication of its report on the Cystogen products to call attention to the way in which a simple drug of established value may be made the basis of an extensive proprietary propaganda. A conservative discussion of the action of hexamethylenamin appears in the Council's publication "Useful Drugs."

Cysto-Sedative

Cysto-Sedative is sold by Strong, Cobb and Company, Cleveland, Ohio, with the claim:

> "Each fluid ounce represents:
> Thuja Occidentalis, 3½ grains.
> Pichi, 18 grs.
> Saw Palmetto berries, 36 grs.
> Triticum Repens, 36 grs.
> Hyoscyamus 8 grs.
> All inert extractive matter being eliminated."

The therapeutically active constituents of arbor vitæ, pichi, saw palmetto and couch grass have never been isolated—indeed, it has not been proved that all of these drugs contain any therapeutically active constituents. Yet the absurd claims are made that all inert matter has been eliminated and each lot of drug used in the preparation of Cysto-Sedative is "tested in reference to its medicinal activity." Equally preposterous is the claim:

> "In formulating Cysto-Sedative each drug entering into its composition was subjected to careful study clinically to determine the exact proportion required when combined to increase their efficiency as a whole. Cysto-Sedative is scientifically prepared, the proportion of each individual drug being *so finely adjusted* as to increase their therapeutic action in the conditions for which they are intended, forming a preparation always reliable and of the very highest medicinal activity."

Some other extravagant claims made for this complex unscientific mixture are:

> "It gives relief in almost every form of cystitis and prostatitis . . ."
>
> "The best results are obtained in the worst chronic cases of cystitis and prostatitis . . ."
>
> "In Cystitis, Urethritis, Prostatitis, Inflammation of the Vesicle Neck, complicated with Gonorrhoea, Enuresis, Painful Micturition, the action of Cysto-Sedative is prompt."

The Council voted that Cysto-Sedative be refused recognition.

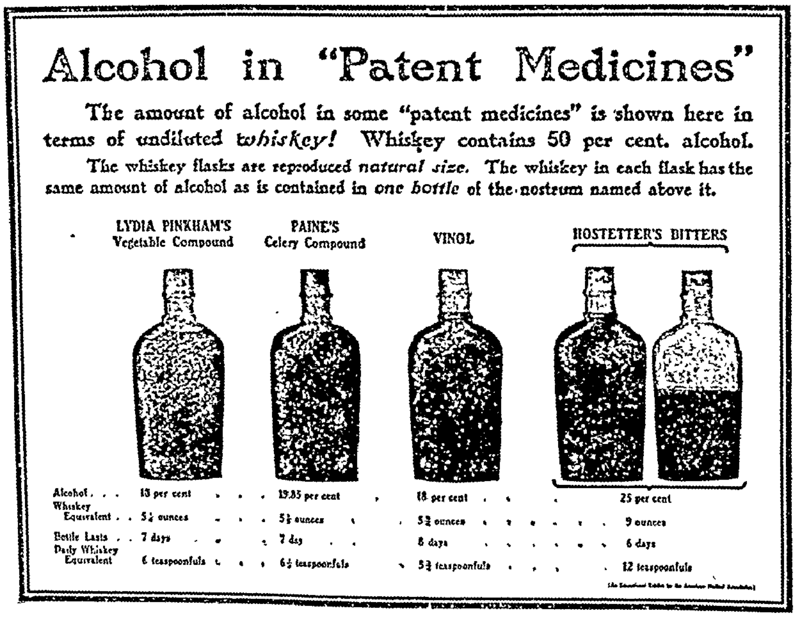
Ergoapiol*

Ergoapiol (Martin H. Smith Co., New York) is a mixture put up in capsules each of which is said to contain

Apiol (Special M. H. S.)	5	grains
Ergotin	1	grains
Oil Savin	½	grain
Aloin	⅛	grain

Examination discloses the fact that, contrary to the claim made, each capsule, instead of containing 5 grains of Apiol, really contains some liquid preparation of the type of oleoresin of parsley seed. Ergoapiol is recommended (on the label) for such diseases as "Amenorrhea, Dysmenorrhea and other Menstrual Disorders," while a circular enclosed in the package contains many suggestions that may be counted on to lead to its indiscriminate and uncritical use.

Ergoapiol is an unscientific, shot-gun mixture of drugs having widely different therapeutic effects. Where the action of parsley is desired, the effects of ergot would ordinarily, be contra-indicated; furthermore, neither aloin or savin would be called for in conditions that demanded the effects of apiol. It would be impossible to predict the action of a mixture of this kind in the varying conditions for which its use is advised by the manufacturers. To combine four drugs of dissimilar action in fixed proportions for the routine treatment of conditions which have little in common except that they involve the female generative organs, is unscientific and absurd. The Council refused admission to Ergoapiol.



Alcohol in "Patent Medicines"

The amount of alcohol in some "patent medicines" is shown here in terms of undiluted *whiskey!* Whiskey contains 50 per cent. alcohol.

The whiskey flasks are reproduced *natural size.* The whiskey in each flask has the same amount of alcohol as is contained in *one bottle* of the nostrum named above it.

	LYDIA PINKHAM'S Vegetable Compound	PAINE'S Celery Compound	VINOL	HOSTETTER'S BITTERS
Alcohol	13 per cent	19.85 per cent	18 per cent	25 per cent
Whiskey Equivalent	5¼ ounces	5½ ounces	5¾ ounces	9 ounces
Bottle Lasts	7 days	7 days	8 days	6 days
Daily Whiskey Equivalent	6 teaspoonfuls	6½ teaspoonfuls	5¾ teaspoonfuls	12 teaspoonfuls

Miniature reproduction of an educational poster prepared by the Propaganda for Reform Department. Twenty-eight different posters already prepared, illustrate various phases of the evils of nostrums and quackery. In the original the placards measure 22 by 28 inches. A catalog of the complete set will be sent on request.

Apergols*

Apergols, put out by H. K. Wampole Co., Inc., is alleged to be a "Uterine Stimulant." Apergols is apparently an inversion of the name Ergoapiol and the preparation appears to have essentially the same formula, namely:

Apiol	5	min.
Oil Savine	½	min.
Ergotin	1	gr.
Aloin	⅛	gr.
Aromatics		q. s.

As in Ergoapiol, the constituent referred to in the formula as "Apiol" appears to be oleoresin of parsley-seed instead of the definite substance apiol described in New and Nonofficial Remedies. In general the claims made for Apergols are the same as those made for Ergoapiol. The Council refused admission to Apergols because they are advertised indirectly to the public, because of unwarranted therapeutic claims, because of the non-descriptive name and because the product is unscientific.

Gastrogen Tablets

The Bristol-Myers Co., Brooklyn, N. Y., sells Gastrogen Tablets which are described as "A Neutralizing Digestive" to be "used in connection with Sal Hepatica." Sal Hepatica, it will be remembered, is another product of the Bristol-Myers Company and has been the subject of previous unfavorable comment. The label on a recently purchased package of Gastrogen Tablets contains the following:

> "For gastric distress, weak stomach and dyspepsia, one to two tablets after eating; repeat in half an hour if needed.
>
> "Also indicated in nausea, flatulence, sour stomach and heartburn."

While these recommendations sound as if they were addressed to the public, Gastrogen Tablets are advertised in medical publications and hence come within the scope of the Council. Gastrogen Tablets are said to be composed of pepsin, calcium carbonate, calcium phosphate and "aromatics." As each tablet, according to the label, contains 7 grains of calcium carbonate (chalk), the recommended dosage would in most cases be sufficient to neutralize the gastric fluids in the stomach and would thus tend to prevent the pepsin from exerting its digestive effects. The means adopted to relieve one symptom of dyspepsia, in other words, defeats the action of the means for relieving the indigestion. The fact is that patients who need an antacid do not need pepsin, while those who need pepsin will be harmed by the administration of an antacid. Gastrologists hold that, except in rare cases, the evidence tends to show that wherever there is a sufficiency of hydrochloric acid there is a sufficiency of pepsin. When pepsin is lacking it should be administered along with hydrochloric acid to make it effective. The Council voted that Gastrogen Tablets be refused recognition.

Iodalia *

Iodalia is sold by Geo. J. Wallau, Inc., with the claim that because of the peculiar combination in which it contains iodin it is a valuable and efficient substitute for iodids. The preparation was examined in the Chemical Laboratory of the American Medical Association, which reported to the Council that, contrary to claim, iodin in the form present in Iodalia, would when administered, act like an ordinary iodid. Further the proportion of iodin present was so small that to administer the equivalent of 20 grains of potassium iodid it would be necessary to give the contents of a one-dollar bottle of Iodalia. In view of this report it is evident that the claim that Iodalia is "always well tolerated" and that it cannot produce "symptoms of iodism" is true only because of the small percentage of iodin it contains. The claims made in the advertising matter, that Iodalia is an efficient iodin medication in the treatment of syphilis, that it is a suitable substitute for cod-liver oil and that it may be used in anemia, dysmenorrhea, dyspepsia, malaria and diseases of the heart, are entirely unwarranted.

Iodalia is exploited in a way to suggest its use to the public for a host of diseases. Particularly reprehensible are the recommendations contained in a circular which accompanies the trade package that Iodalia:

> ". . . offers the same protection against grippe, bronchitis, pneumonia, tuberculosis, pleurisy and other infectious diseases that vaccine does against small pox . . ."
>
> "It is also the best preventive against the slight infections and ailments to which debilitated and delicate children are subject."

The Council voted that Iodalia be refused recognition.

Iodotone*

Eimer and Amend, New York, who market Iodotone, state that it is a solution of hydrogen iodid (hydriodic acid) in glycerin, containing 1 grain of iodin to each fluidounce. The unwarranted assertion is made that Iodotone

> ". . . will produce the constitutional effect of iodine in a shorter time than other preparations . . ."

This cannot be true, for it is certain that, because of the alkaline reactions of the tissues, iodids, whether administered as hydrogen iodid or as alkali iodids, must circulate in precisely the same form and therefore exert the same therapeutic effects in precisely the same way.

Eimer and Amend further assert that the ordinary iodids may to advantage be replaced by Iodotone. The absurdity of this claim is apparent when it is considered that it will be necessary to administer nearly one fluidounce of glycerin to obtain an amount of Iodotone equivalent to a 10-grain dose of potassium iodid. The additional claim that Iodotone will not disturb the stomach or produce the usual disagreeable symptoms of iodism is evidently unwarranted, for it is generally conceded that symptoms of iodism can be avoided only at the risk of insufficient iodin medication. Because of these unwarranted and misleading claims and because the name Iodotone would tend toward the uncritical use of the preparation as a general tonic, the Council voted that Iodotone be refused recognition.

Nourry Wine*

Nourry Wine (E. Fougera and Co., New York) is a proprietary iodin preparation said to contain 12 per cent. of alcohol and 1½ grains of iodin in combination with tannin to the fluidounce. Experiments made in the A. M. A. Chemical Laboratory demonstrate that the iodin contained in Nourry Wine is present either in the form of iodid ions or in a form very readily yielding iodid ions and that therefore its action will be that of ordinary iodid. Yet a circular asserts:

> "The Nourry Wine is the one preparation . . . able to introduce into the organism the active metalloid liberated little by little from the organic combination . . ."

While Nourry Wine contains but an insignificant proportion of iodin, the circular claims that "Nourry Wine presents a high dose of iodin." Further, the label on Nourry Wine and the circular which is wrapped with it suggests its use in a number of diseases in which iodin medication is considered of minor importance. These recommendations, bolstered up by testimonials from twelve to twenty-five years old, are likely to lead the public if not the medical profession to use this weak iodid wine where efficient treatment is called for. The attempt is made to give a further false value to Nourry Wine in the minds of those who prize everything that is foreign by the suggestion that it comes from France when in reality it is made in New York. In conclusion the Council held that, though the alcohol of the wine is the most potent constituent, the constant use in the advertising matter of the term "Nourry Wine," unqualified by the adjective "Iodinated," was mischievous as likely to lead to the thoughtless use of the preparation in cases unsuitable for iodin medication. The Council refused recognition to Nourry Wine.

Correspondence

Postgraduate Study; Foreign Realities Versus American Remedies

To the Editor:—We all know the enthusiasm with which American physicians have sought the European clinics of Berlin and Vienna for postgraduate medical work. Hundreds of physicians each year flock thither. They stay varying lengths of time but generally are content with a few weeks or two or three months at the most. To the average layman such study in Europe casts a halo of superiority about the physician possessing it. It is a matter of common parlance to say, "Dr. So and So, yes, he has studied abroad, in Vienna." Most physicians in this country who are doing serious work and who are unable to go abroad for study look on Berlin or Vienna as their Carcassonne. If they never attain it, it remains a source of lasting regret or constant longing. Physicians will often make great sacrifices in order to visit the foreign clinics. Many of them are uncritical and easily persuaded of the tremendous advantages of the work. Some are frankly doing it just for a good time and for the advertisement which they know such a vacation will bring them on their return. But I am convinced that there is an ever-increasing number of physicians who go with all enthusiasm and expectation and who come back disappointed and disillusioned about foreign study. This in no way is a reflection on the medical profession in Germany, for they are only supplying the demand of the American physician and giving him what he wants. Neither does this statement apply to those who spend a year or more in serious work in a foreign clinic. But *they* are relatively few. They generally remain at one clinic and do not put in an appearance at the large centers.

The Germans are just beginning to appreciate American medicine and to read American literature. Why they have been so slow in recognizing the high standard of our work may be partly constitutional, but is, I think, much more directly due to the impression which American physicians studying abroad make. They are undoubtedly not representative of the best in the profession in America. The Anglo-American organization in Berlin and the American Medical Association of Vienna are partly responsible, in that they encourage the quick-lunch variety of study and have so organized special monthly courses for foreigners that it is almost impossible to make the Germans believe that we are not all quasi-quacks. The physician receives his medical pabulum as rapidly and in as large doses as he can pay for it. Go to any lunch counter at home and you may see a similar sight. All the crudities and mannerisms for which we are caricatured are in evidence, from the method of handling table utensils to the manner of stoking food and the peculiarities of our national tastes. Go to Vienna and you can see the same phenomena at the medical lunch counter. Some are there for one month and they gorge themselves, eating much and digesting little. Others are there for the side shows and the beer and take only food enough to get their certificate, which the University of Vienna issues to any one who can pay the price of a course whether he attends or not. Generally courses are served up in German and so rapidly served that the average American loses the meat and gets only the names. Sometimes the attempt is made to furnish English dishes, and then the job is generally botched. The German language alone is an all-sufficient argument against postgraduate study for the average American physician. All the teaching is didactic, and this again condemns it from the point of view of serious work in modern medicine. The laboratory method is after all the only safe one. In Vienna, you find men taking the most indigestible mixtures. Surgeons "brushing up" in neurology, gynecologists taking a little dab from the "Freudian School," many men listening to the refinements of differential diagnosis, who know almost nothing of the fundamentals. Most of the patrons of this great medical lunch counter get wildly enthusiastic, but they understand little of what they are eating and you are reasonably certain that they will have mental indigestion of the worst kind if they do not actually become seasick on their return and lose it all. What few misgivings they may have are obliterated by the general air of enthusiasm and the thought that nobody at home is any the wiser.

Without the slightest danger of being called snobbish, the average American physicians in Vienna most of us wish to avoid. Their absence is more flattering to our pride than their presence. Many of them are avowedly on a vacation. Others frankly say that their community only needs to be told that a man studied in Berlin to increase its respect for him. One man told me that he must visit Berlin before he returned as it was regarded as *the* center in his community. I suggested in joke that it might be enough to ride through and he acquiesced in all seriousness and I afterward learned that he spent one afternoon in Berlin on his way home. Such instances are not uncommon. A larger number, however, are perfectly sincere, but do not recognize how little they are really getting for their money and how infinitesimal is the knowledge which they carry home with them. These physicians go because it is the thing to do and they stay when they get there because they are uncritical and do not realize the absurdity of it all.

Physicians at large do not as yet appreciate the laboratory method in medical education and still cling to didactic teaching. It is a much easier thing to eat a meal set before you than to prepare the meal for your own delectation. But you cannot learn cooking from eating; neither can you learn medicine from hearing it taught.

A further reason for the continued popularity of foreign study is the fact that the general public is also in ignorance of its real value. It is our duty to set the facts before the public and enlighten them so that the name of "specialist" appended to one who has lived in Vienna for a few weeks will not be the open sesame to a lucrative practice.

Our other clear task lies before us: the efficient organization of postgraduate study here at home. We have all the facilities but lack organization. Now that the foreign market is closed, this is not only a duty but an imperative necessity and will be an opportunity for advancement and growth in this country to which the opprobrium of self interest cannot be attached. Whatever outside commercial advantages may come to us through the war they are far less important than the development of our own resources through cooperation and organization within our own borders.

The impetus given to postgraduate education in this country by the European war will be tremendous. Foreign centers of education will inevitably lose prestige. The tide will turn so that we may be the recipients of the European student as we are now of the European laborer.

Let us at once set to work and organize ourselves for this task and give to American physicians practical postgraduate work in *our own* language and with our own *trade-mark*.

Hugh Payne Greeley, Boston.

Traffic Officers' Neuroses

To the Editor:—In looking over medical literature for the past ten years, I can find no records of any trouble with the traffic officer which may be due directly to his occupation. Within the last year a few cases came under my observation, and I will only refer to them here preliminary to a more complete report in the future. It would be interesting to know if men in other cities have observed symptoms similar to those I mention here. This being an age of prevention rather than cure, I believe we may possibly do something for the poor traffic officer who stands on a dusty, busy corner all day long blowing an "ear-splitting," mouth-irritating, and if I may use a harsher term, "saliva-slobbering" whistle. The symptoms reported here usually disappear after the first six months of the officer's duty, with the exception of the chronic bronchitis and tendency to deafness. The syndrome which was uniformly present in the few patients who have consulted me so far is as follows:

Pain in the sternomastoids and soreness in the masseter muscles; also pains radiating to the shoulder via the trapezii, and soreness in the epigastrium, noticed particularly on pressure or when the patient sits down. There was tinnitus aurium and slight deafness. There was ptyalism and mild parotitis, but I could elicit no crepitus in the parotids such as we find in glass-blower's or musician's disease. There was pharyngitis, bronchitis and cough in the morning. All complained of intense hunger, stating that they had to eat five or six times a day. As to the etiology of the foregoing symptoms, I will say without hesitation that the whistle is either directly or indirectly responsible. I believe the pains radiating to the shoulders and back of the neck by way of the trapezii are due to the fact that the officer takes a sudden inhalation before blowing so many times a day, always bringing these muscles into play. The pain in the masseters is due to the officer developing a habit of holding the whistle between his teeth between times.

So far I have found soreness in the epigastrium only in stout men, which I think is due to sudden jarring of the stomach when blowing the whistle. The ptyalism and mild parotitis I think is chiefly due to the parotids and other salivary glands being constantly stimulated by the metal whistle. The tinnitus aurium and slight deafness is probably due to the officer ballooning the ear-drums and eustachian tubes so often during the day, and also to noise. One man, who had been on the force on a prominent corner for seven years, complained of gradual and progressive deafness.

The irritated mouth is directly due to the whistle, and who knows, as those men get older, but that a more malignant trouble may develop? I mean epithelioma of the lip. The bronchitis is due to sudden inhalations of dust particles directly into the bronchi with the mouth open just before the officer blows the whistle.

The hunger is probably due to the ptyalism, and also of course to the officer being in the fresh air.

I will state here that those who have consulted me so far declare that they never had any of those troubles before they became traffic officers, and on resting and withdrawing the whistle for a few days most of the symptoms disappeared.

A. J. Caffrey, M.D., Milwaukee, Wis.

Crotalin in Epilepsy

To the Editor:—The concluding paragraphs of the article on "Crotalin in Epilepsy," by C. L. Jenkins and A. S. Pendleton (The Journal, Nov. 14, 1914, p. 1749), indicate that the convulsions of epileptics are increased by its use and that it has no beneficial effect on the mental condition of the patient. In spite of this, and in spite of the dangers pointed out by Anderson and others, the wording of the authors might be interpreted to mean that they condone or perhaps even invite its use because it satisfies "the abnormal craving for medicine which all epileptics have." I feel certain that this was not their intention, and that they really wished to explain that any apparent benefits are due simply to the psychic effects of "doing something"; but unless they state their position more clearly, it may be feared that it will lead to the uncritical use of crotalin and to the haphazard, ill-considered use of medicine in general.

C. W. Stone, M.D., Cleveland.

[This letter was referred to the authors who replied:]

To the Editor:—In reply to the comment regarding our paper on "Crotalin in Epilepsy," we wish to say in no uncertain terms that it was not our purpose either to condone or to invite the use of this substance.

The sentence criticized was added to account for the apparently good effects occasionally seen in the beginning of its use in certain isolated cases.

In our experiments we believe that a sufficiently large number of cases were treated over a sufficiently long period to eliminate possible sources of error, and our conclusions as stated were that the drug did harm and, so far as we could determine, no good. The sentence was added as a warning to those who might imagine that they were obtaining good results in the beginning of treatment.

C. L. Jenkins, M.D., and A. S. Pendleton, M.D.,
Raleigh, N. C.

The New Conception of the Family Physician.—While I realize that it is the ultimate aim of public hygiene to make the physician in the sense of a pill peddler superfluous, I appreciate equally well that he will be all the more needed to practice medicine in the modern sense of the word. . . . But where is the field of the general practitioner, I hear some ask. He is the family adviser as he has been in the past but on a more scientific basis—he is the family health adviser if not the family physician and his relation to each of "his families" is even more sacred than in the days of old. He is expected to keep the baby well, not merely to give it medicine when ill; he is called in to examine the children of school age from time to time and to give advice as to their work and play; he is asked to pass on the health of the youthful son and daughter and find out why this loss of weight or want of appetite, and he must keep track of father and mother to see that they do not work and worry so much that their health may be impaired or their lives shortened.—Guy L. Kiefer, *Jour. Mich. State Med. Soc.*

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

HAND LOTIONS AND CHAPPED HANDS

To the Editor:—Please furnish me a formula for a hand lotion to be used in offices where it is necessary to wash frequently. I do not mean an antiseptic, but something to prevent chapping and irritation of the skin. R. S. Goux, M.D., Detroit.

Answer.—Hand lotions are generally of two types: (1) glycerin solutions of the glycerin, rose water and benzoin kind, and (2) gelatinous liquids made with tragacanth, quince seed, or some other water-soluble colloid. The glycerin lotions work well with some skins and are the most satisfactory to an occasional individual, but as a rule they are not the best, first, because the glycerin tends to make drier a skin already too dry, and, second, because these lotions have little or no detergent effect and do not clean the skin.

The tragacanth and quince seed lotions are better, and of these the tragacanth lotions are certainly as good as any other and are very cheap and easy to make. A formula for such a lotion given by Pusey is as follows:

Tragacanth	gr. 80
Glycerin	℥ ss
Boric acid	ʒ ss
Water ... q. s.	Oi
Oil of bergamot	♏ iv
Oil of lavender	♏ ii
Oil of rose	♏ i

The oils mentioned being added as a perfume might be omitted, one or all of them, according to the wish of the prescriber.

The boric acid, glycerin and waters are first mixed, the tragacanth added and the mixture agitated until the tragacanth is dissolved. This makes a rather thick mucilage; it can be changed to any consistency desired by slight increase or decrease in the amount of tragacanth.

A lotion like this has a considerable detergent effect; it is a tolerable substitute for soap, and if it is freely rubbed over the hands and wiped off, either with or without the use of water, cleans the skin of all but the most tenacious dirt. It, of course, cannot be effectually used as a complete substitute for soap. Such a lotion has the advantage over soap that it not only is not irritating to sensitive skin but also is bland and soothing. It thus tends to prevent and eventually to cure chapping of the hands.

The chief reason for chapping of the hands is the lack of fat in the skin in cold weather. Fat production in the skin is at a minimum in cold weather, because of the diminished sebaceous and sweat secretion. This and the dry air of winter make the skin dry and vulnerable at the very time when the cold air is itself irritating. This combination leads readily to chapping, if the hands must be exposed much to soap and water, and particularly if the irritation of antiseptics is added, as in the case of physicians and nurses.

The first thing to do to prevent or overcome the condition is to supply, by greasing the skin occasionally, the lacking fat in the skin. Almost any bland fat or semisolid hydrocarbon will do for this purpose, but nothing is better than a well-made cold cream. The next and the more difficult thing to do is to avoid soap and water—especially soap—as much as possible; and it is here that hand lotions serve a very useful purpose.

LITERATURE ON MENSTRUATION

To the Editor:—Please let me know of any small works there may be on the subject of menstruation. D. A. S., M.D., Manitoba.

Answer.—The following is a list of references on this subject:

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Alabama: Montgomery, Jan. 5, 1915. Chairman, Dr. W. H. Sanders, Montgomery.

Alaska: Juneau, Jan. 5, 1915. Sec., Dr. H. C. DeVighne, Juneau.

Arizona: Phoenix, Jan. 5-6, 1915. Sec., Dr. John Wix Thomas, 200 Nat'l Bank of Ariz. Bldg., Phoenix.

Illinois: Chicago, Jan. 13-15, 1915. Sec., Dr. C. St. Clair Drake, Springfield.

Indiana: Indianapolis, Jan. 12-14, 1915. Sec., Dr. W. T. Gott, State House, Indianapolis.

Iowa: Des Moines, Jan. 19-21. 1915. Sec., Dr. Guilford H. Sumner, Capitol Bldg., Des Moines.

Kentucky: Louisville, December 16-18. Sec., Dr. A. T. McCormack, Bowling Green.

Maryland: Homeopathic, Baltimore, December 15-16. Sec., Dr. O. N. Duvall, 1817 N. Fulton, Baltimore.

Minnesota: Minneapolis, Jan. 5-8, 1915. Sec., Dr. Thomas McDavitt, 814 Lowry Bldg., St. Paul.

Missouri: St. Louis, December 14-16. Sec., Dr. J. A. B. Adcock, State House, Jefferson City.

New Hampshire: Concord, December 29-30. Regent, Mr. H. C. Morrison, Concord.

New Mexico: Santa Fe, Jan. 11, 1915. Sec., Dr. W. E. Kaser, E. Las Vegas.

North Dakota: Grand Forks, Jan. 5, 1915. Sec., Dr. G. M. Williamson, Grand Forks.

Oklahoma: Oklahoma City, Jan. 12-14, 1915. Sec., Dr. John W. Duke, Guthrie.

Rhode Island: Providence, Jan. 7, 1915. Sec., Dr. Gardner T. Swarts, State House, Providence.

South Dakota: Pierre, Jan. 12, 1915. Sec. Dr. P. B. Jenkins, Waubay.

Utah: Salt Lake City, Jan. 4-5, 1915. Sec., Dr. G. F. Harding, 407 Templeton Bldg., Salt Lake City.

Vermont: Montpelier, Jan. 11-13, 1915. Sec., Dr. W. Scott Nay, Underhill.

Virginia: Richmond, December 15-18. Sec., Dr. J. N. Barney, Fredericksburg.

Washington: Walla Walla, Jan. 5, 1915. Sec., Dr. C. N. Suttner, Baker Bldg., Walla Walla.

Wisconsin: Madison, Jan. 12-14, 1915. Sec., Dr. John M. Beffel, 3200 Clybourn St., Milwaukee.

Idaho April Report

Dr. John F. Schmershall, secretary of the Idaho State Board of Medical Examiners, reports the written examination held at Wallace, April 7-8, 1914. The total number of subjects examined in was 11; total number of questions asked, 110; percentage required to pass, 75. The total number of candidates examined was 15, of whom 13 passed and 2 failed. Two candidates were licensed through reciprocity. The following colleges were represented:

PASSED College	Year Grad.	Per Cent.
University of Colorado	(1912) 80; (1913)	84.5, 87
George Washington University	(1910)	89
College of P. and S., Chicago	(1902)	80
Jenner Medical College	(1897)	83

Book Notices

BLOOD-PRESSURE: ITS CLINICAL APPLICATIONS. By George William Norris, A.B., M.D., Assistant Professor of Medicine in the University of Pennsylvania. Cloth. Price, $3 net. Pp. 372, with 99 illustrations. Philadelphia: Lea & Febiger, 1914.

The advance of medical knowledge and the more intimate correlations of experimental and clinical observations are evident in the books recently published on the subject of blood-pressure. The work of Norris is an attempt to exhibit this subject in a thorough manner with reference to its scientific relations. The facts of physiology are briefly given and these are followed by a thorough explanation of the methods of determining blood-pressure. Various instruments are described, the relative advantages of the different methods shown and some advice given as to the choice of an instrument. Venous and capillary pressure are discussed briefly as befits their minor clinical importance. Methods of determining functional efficiency of the circulation are described at considerable length. The rest of the book, comprising about one-half of the volume, is concerned with the clinical applications. Hypotension and hypertension are discussed. Here the author shows his conservatism in that he insists that neither of these conditions is per se an indication for therapeutic interference. Low blood-pressure may be a provision of nature for economy of energy and demands no treatment unless there is evidence of a progressive condition. Similarly, he insists that hypertension is an adjustment of nature which should not be interfered with directly, but changes should be effected by reaching the cause of the hypertension. "We must never thoughtlessly or ruthlessly interfere with Nature's delicately balanced mechanism of compensation. Only in the face of impending circulatory failure of vascular rupture or temporary pain is direct treatment indicated. . . . Just how much pressure lowering is possible and desirable must be determined for each individual case, and in no instance is such an effect to be sought merely by the administration of drugs." The hypotensive action of radio-active substances is briefly described. Chapter 14 gives an alphabetical list of remedies, drugs and glandular extracts, describing their effect on arterial tension and their therapeutic use. This list seems to be especially complete as it includes some drugs like mistletoe which are not described in ordinary books on pharmacology. Throughout the clinical part the discussion is conservative and judicial, while at the same time it exhibits an amount of research which inspires confidence in its reliability. We believe that this thoroughness and exactness, together with the practical treatment given various subjects, will secure for the present work a place in the first rank of treatises on this important subject.

THE CURE OF ALCOHOLISM. By Austin O'Malley, M.D., Ph.D., LL.D. Cloth. Price, $1.25. Pp. 312. St. Louis: B. Herder, 1913.

The subject of alcoholism is viewed by the author from a broad point of view more as a moral and religious defect than as a purely physical ailment. Hence, he insists that the cure of alcoholism can be achieved only by the cultivation of the virtues, of which sobriety is only one manifestation which cannot be expected to exist alone.

Only a small part of the book is devoted to the medical aspects of the subject. The physiology and pathology are given more with reference to the instruction of lay readers than to physicians. A large space is given to the discussion of the relations of alcoholism to heredity and alcoholic imbecility. The physical treatment of alcoholism is considered in Chapter 5 and is in accord with the best modern treatment. The rest of the book is given to religious and theologic discussions which take a somewhat wider range than the mere consideration of drunkenness. The author seems liable to occasional, rather sudden, digressions. For instance: In the chapter on the ethics of drunkenness, several pages are given to the description of poisonous serpents and the treatment of snake poisoning in which other measures are recommended, but not alcohol. The author discusses moral means for the cure applicable to non-religious or non-Catholic individuals and the supernatural control of intemperance in which the cooperation of religion is discussed. An appendix is devoted to the subject of opium and other drugs. While not all readers may be disposed to agree with the author's theology, a perusal of this book cannot help but call attention to phases of the treatment of alcoholism which are apt to be much neglected.

NUTRITION. A Guide to Food and Dieting. By Charles E. Sohn, F.I.C., F.C.S. Cloth. Price, $1.25. Pp. 256, with illustrations. New York: E. B. Treat & Co., 1914.

This book appears to be intended as an elementary treatise on dietetics. The author seems to be strongly impressed with the danger in the United Kingdom from the prevalence of dyspepsia. He states that it is calculated that there are in the United Kingdom at least 8,000,000 persons suffering from dyspepsia in some shape or form. This is a strange admission in view of the frequent characterization by English writers of the United States as a nation of dyspeptics. The statement of facts in the book is in general correct and clear. Ventilation is discussed from the point of view of the contamination of air by products of respiration. In this section the author seems to have taken no notice of modern teaching with regard to the nature of foul air. The book seems to be quite free from any tendency toward fads and there is no evidence of the influence of proprietary interests. The author notices the standard of protein requirement advocated by Chittenden but does not favor its adoption. The consideration of alcohol is apparently entirely favorable to its use as a food. The book contains a large amount of valuable information and, while it is not complete as a medical text-book on dietetics, it would be of great value for the use of intelligent laymen.

THE PROBLEM OF THE NATIONS. A Study in the Causes, Symptoms and Effects of Sexual Disease and the Education of the Individual Therein. By A. Corbett-Smith, M.A., F.R.G.S. Cloth. Price, $1 net. Pp. 107. New York: Paul B. Hoeber, 1914.

This is an English publication embracing a study of the causes, symptoms and effects of sexual disease and the necessity of the education of the individual therein. As the author states in his introduction, it is not intended as a scientific research but is an effort to place before the lay reader a plain straightforward account of the dangers of venereal infections. The fact that the writer is a lawyer and not a physician really increases the strength of the appeal, while the facts are presented in an entirely different manner from any of our American publications in this field. The facts themselves are naturally very much the same. Probably the method of presentation will make more of an impression on young men than anything which American writers have evolved. It is written specially for the young man beyond the schoolboy age. The style is plain, straightforward and thoroughly manly throughout without any moralizing, unnecessary sentimentality or undue appeal to fear. The writer knows the class to whom he appeals and his book is more like a personal, free conversation or letter than like a moral pamphlet.

I. K. THERAPY WITH SPECIAL REFERENCE TO TUBERCULOSIS. By W. E. M. Armstrong, M.A., M.D., Bacteriologist to the Central London Ophthalmic Hospital. Cloth. Price, $1.50 net. Pp. 83. New York: Paul B. Hoeber, 1914.

The paucity of references to I. K. in the literature of the past three years would seem to justify the conclusion that Spengler's method had failed to make good. The sporadic appearance of a few articles from American authors seems to have aroused no general interest. The method seems to have been imported into England, and the present work represents an effort to popularize it in that country. The author takes the part of an advocate. Considerable space is given to an exposition of the well-known principles of immunity. When special reference is made to I. K. he seems to be content with assertion merely. No proof is given of the statements of Spengler. It is assumed as a fact that the red blood-cells contain the bulk of the immunizing substances in the tissues of immune animals. The clinical results are detailed without a hint that any unfavorable results have been obtained. There is no notice of the controversy which has occurred regarding this treatment or of the published statements of its worthlessness. The author gives a bibliography which includes a number of authors who have given unfavorable reports, but nothing is said of their reports. The book must be regarded as non-critical and chiefly useful as giving an idea of the theory and method of Spengler which could be given for intelligent medical men in much less space.

Rose and Carless's Manual of Surgery for Students and Practitioners. Ninth edition. Revised by Albert Carless, M.B., M.S., F.R.C.S., Professor of Surgery, King's College Hospital, London. Cloth. Price, $6 net. Pp. 1408, with 609 illustrations. New York: William Wood & Co., 1914.

The eighth edition of this book appeared in 1911, and as the author states, the three years since have not been characterized by any revolutionary or wonder-working novelty. However, "salvarsan and radium in particular may be mentioned as subjects to the consideration of which a vast amount of work has been devoted. Salvarsan stands as the conqueror of the worst ill effects of syphilis, if only it be employed in time; radium has proved itself a potent agent for good in many cases, but the magniloquent prophets who hailed it as the victor of cancer have not yet proved their claims." A new chapter is added on the use of heat, light, electricity and radium, as well as new illustrations and colored plates. The book is printed on thin paper, making the volume light in weight and convenient for handling. The author adds a personal note by saying:

> "I trust that this edition may prove even more helpful than those which have preceded it, and pray that when the tenth edition is required the sounds of war strife, which boom on the ear as these lines are penned, may long have ceased, and that a righteous peace leading to a happy competition of race with race in the effort to promote, not the destruction, but the welfare of mankind of all nationalities may have been established."

Let us hope with him that not too long a period passes before the tenth edition appears.

Tropical Diseases. A Manual of the Diseases of Warm Climates. By Sir Patrick Manson, G.C.M.G; M.D., LL.D., Lecturer in the London School of Tropical Medicine. Fifth edition. Cloth. Price, $5 net. Pp. 937, with 255 illustrations. New York: Williaim Wood & Co., 1914.

The fourth edition of this work appeared in 1907. Since that time great advances have occurred in the field of tropical medicine, relating to beriberi, yaws, verruga, sleeping-sickness and pellagra. In the preface the author states that while tropical pathology has been actively and successfully studied, prevention and treatment of tropical diseases have also not been neglected; such newer investigations of a practical nature are also included in the new edition. A few which are mentioned for example are the treatment of yaws and relapsing fever by salvarsan, the treatment of trypanosomiasis by antimony, and perhaps the most important of all, the substitution of emetin for ipecac in the diagnosis and treatment of amebiasis. The work is full of valuable illustrations, including colored plates and instructive charts. The parasites and various flies which act as carriers are fully illustrated. American and English surgeons and physicians whose work carries them into these tropical zones, as well as those men of broad knowledge who follow the entire field of medicine, know the valuable nature of this work.

Life and Law. The Development and Exercise of the Sex Function, Together with a Study of the Effect of Certain Natural and Human Laws and a Consideration of the Hygiene of Sex. By Maude Glasgow, M.D. Cloth. Price, $1.25 net. Pp. 194. New York: G. P. Putnam's Sons, 1914.

This is another of the numerous books recently written for women on sex and its various problems. The point of view of the writer is that of a moderate feminist. The attitude of the writer can best be illustrated by a quotation from Chapter 12, in which the development of women and her social and legal status is under discussion: "Even as late as the present century a male writer declared that 'the function of reproduction alone excused or explained woman's existence.' The writer to whom reference has been made apparently was not aware that biologic research had shown that it was the male sex that was created solely to save the race and as an afterthought of nature." While the book gains some novelty on account of this point of view and is worth reading by the careful student of present-day problems, it does not contain any original material or anything that is a special contribution to the discussion.

Infection and Resistance. An Exposition of the Biologic Phenomena Underlying the Occurrence of Infection and the Recovery of the Animal Body from Infectious Disease. By Hans Zinsser, M.D., Professor of Bacteriology at the College of Physicians and Surgeons, Columbia University, New York, with a Chapter on Colloids and Colloidal Reactions by Prof. Stewart W. Young. Cloth. Price, $3.50 net. Pp. 546. New York: The Macmillan Company, 1914.

The practical importance of the subject of immunity, in both the prophylaxis and the treatment of disease, is calling forth a number of excellent works on the subject. The present book must be reckoned among the best of those that have appeared for the use of the physician. The study of the subject is both thorough and practical. The method of vaccine therapy is discussed and in many cases the evidence for the value of this method of treatment is given at some length. The book, however, does not quite take the place of a comprehensive work on vaccine therapy. In addition to the discussion of the subject of anaphylaxis, supplementary chapters are given on Abderhalden's work on protective ferments and on colloids. The statement of facts in general is concise and clear. The book is well illustrated with drawings, several of which are colored.

The Next Generation. A Study in the Physiology of Inheritance. By Frances Gulick Jewett. Cloth. Price, 75 cents. Pp. 236, with illustrations. Boston: Ginn & Co., 1914.

This is one of the Gulick Hygiene series. Its dedication to boys and girls, the guardians of the next generation, as well as the specific statement of the author in the introduction that the purpose of the book is to let young people know the perils which threaten them and how to avoid them, place the book in the rapidly growing group of publications for the sex education of boys and girls. Mrs. Jewett's antecedents, training and experience have given her an unusual equipment for such a task. This book is perhaps from a constructive point of view the best prepared of any of the recent publications in this field. It is well illustrated, unusually well printed and should prove a valuable addition to the series to which it belongs.

A Manual of Physiology with Practical Exercises. By G. N. Stewart, M.A., D.Sc., M.D., Professor of Experimental Medicine in Western Reserve University. Seventh edition. Cloth. Price $4 net. Pp. 1132, with 467 illustrations. New York: William Wood & Co., 1914.

The period of use represented—from 1896 on—has shown that Stewart's text-book may be depended on to keep pace with modern advances in this particular field. The seventh edition has been extensively revised. The chapter on metabolism has been enlarged and much of it rewritten. Great changes have been made in those portions devoted to the blood-gases, enzymes, nervous system, etc. A change in arrangement is made by dividing the longer chapters into sections and increasing the number of chapters. Many new illustrations and new drawings of old illustrations add in the improvement of an already good work.

A Text-Book of Pathology. With a Final Section on Post-Mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., LL.D., Emeritus Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia University, and T. Mitchell Prudden, M.D., LL.D., Emeritus Professor of Pathology, College of Physicians and Surgeons, Columbia University. Tenth edition. Revised with the cooperation of Francis Carter Wood, M.D., Director of Cancer Research, Columbia University. Cloth. Price, $6 net. Pp. 1116, with 708 illustrations. New York: William Wood & Co., 1914.

The latest issue of this well-known book embodies recent advances in pathology. It quotes numerous references from recent literature and in its illustrations and arrangement maintains the excellent standard of previous editions.

Miscellany

Source and Supply of Drugs

We have previously commented on the likelihood of a shortage in drugs and the consequent increase in prices to be expected as a natural outcome of the European war. In *Public Health Reports* for October 9, Wilbert says that probably the chief reason for the rapid rise in prices was the fact that the available stocks of many of the staple articles during the summer months are usually at a rather low level, and that practically all of the great drug markets of the world are in the war zone, so that stocks on hand in these ports are not available for shipment. By far the greater number of drugs sold throughout the world are marketed via London, Hamburg or Trieste. A few products of the Dutch colonies are sold through Amsterdam, and some of the drugs produced in Turkey and Western Asia come directly from Constantinople. Many vegetable drugs deteriorate on keeping. These, known as botanicals, are usually kept on hand only in small quantities, and supplies are not kept over from year to year. The greatest difficulty in securing supplies of drugs during the coming year, however, will no doubt be encountered, Wilbert thinks, in connection with the so-called "synthetics." Practically from its beginning this business has been monopolized by European manufacturers. Even the simplest drugs, like benzol, anilin oil, phenol (carbolic acid), salicylic acid and benzoic acid, are produced almost exclusively in Europe. Benzoic acid is being quoted at ten times the price at which it could be purchased a month before the war. Salicylic acid is five times higher, and phenol ten times the price asked before hostilities began. Another example of this type is thymol. This article was quoted in July at approximately $2 per pound, while in October $15 a pound is asked, and the available stock is practically exhausted. This is true despite the fact that in this country there are unlimited amounts of the raw material. Much domestic coal-tar was previously sent to Europe to be there manufactured into numerous products, which were sent back to America with enhanced value. Farmer's Bulletin 188, entitled "Weeds Used in Medicine," contains illustrations of a number of drug plants and the necessary directions for gathering and curing many of the drugs which are now scarce. This pamphlet may be obtained by addressing the Superintendent of Documents, Washington, D. C. Needless to state, many of the alkaloids, such as cocain, morphin and quinin, will be widely used in the countries now at war, and the increased demand will result in higher prices. It is to be hoped, says Wilbert, that this particular burden of the war may have a remedying feature in that it will teach us to exercise greater care in the use of these commodities, will tend to encourage their production in this country, and will suggest the practicability of establishing for ourselves, and for the American community generally, a distributing center for the drug products of the world that will be independent of the now existing drug depots in European ports.

Treatment of Diabetes Fifty Years Ago

It is interesting occasionally to "hark back" and see behind the scenes fifty years ago. Occasionally such opportunities are offered in letters that were written "not for publication." Dr. R. L. Wilbur of San Francisco forwards us a copy of a letter written to his father by Dr. A. B. Palmer, a member of the Medical Department of the University of Michigan. Dr. Palmer held various positions in that university; according to our records he was professor of anatomy in 1852-1854; of materia medica, therapeutics and diseases of women and children, 1854-1860; of the theory and practice of medicine, pathology and materia medica, 1860-1861; of the theory and practice of medicine, and of pathology, 1861-1864; of pathology, the practice of medicine and of hygiene, 1864-1869; of pathology and the practice of medicine, 1869-1880, and of pathology and the practice of medicine and clinical medicine, 1880-1887. Dr. Palmer was a graduate of the College of Physicians and Surgeons of the Western District of New York in 1839, and died Dec. 23, 1887.

Dr. Vaughan, in a communication to the editor, states that Dr. Palmer, in his time, was a strong man in the profession, a thorough student, and availed himself of every opportunity to increase the width and scope of his professional knowledge, and that he was a great teacher, and always stood for the best in the profession.

Following is the letter:

D. L. Wilbur, Esq.

Dear Sir:—Your letter is at hand asking advice about your brother, who you say is affected with diabetes. It is always very unsatisfactory to treat a patient without seeing him, and you are not very full in your description of the case. I assume, however, that he has diabetes, passes a very large quantity of urine loaded with sugar, etc., and that there is no particular complication requiring attention. The disease, you are aware, is a very severe one, often—I may say generally—proving fatal sooner or later, and very soon in rapid and severe cases. The pathology and treatment (medicinal) is not as well established as in most other diseases, but the dietetic treatment is most important and is pretty well settled. The patient must avoid sugar and starchy foods as much as possible. All forms of sugar must be discarded entirely and bread, potatoes and fruit containing starch and sugar must be avoided as much as possible. He should live on fresh meat, eggs, soups, cheese (if it agrees), butter. Milk contains sugar, and much of it would be objectionable on that account.

Some persons cloy on these articles readily and need something in addition. The following kind of bran bread may be taken with the meat diet; Put 1 pound of bran in an oven, hot, for one-fourth hour; when warm and crisp grind in a fine coffee mill or pepper mill; mix with it half a pound of butter and the yolks of six eggs, 1 teaspoonful of bicarbonate of soda, and milk enough to make into a paste. Divide into cakes and bake in a quick oven. These cakes may be taken with butter or cheese.

Or another: 3 ounces of bran, 3 eggs, 1½ ounces of butter, 7 fluidounces of milk. Mix for a loaf. Just before putting it into the oven, add, mixing in with it, 35 grains of bicarbonate of soda and 3 drams of dilute hydrochloric acid. Bake in a basin well buttered for an hour or more. One of these kinds of bread to be used with the meat in place of ordinary bread or potatoes. There would be no objection to occasionally taking some tomatoes, or greens in the proper season. If vegetable substances be much craved for and the stomach seems suffering for them, a baked apple may be taken once in a few days. The skin should be kept warm, well clothed (flannel), and the warm bath—or quite as well warm sponge bath—should frequently be practiced. Must not remain in a warm bath too long as it debilitates—10 minutes or more—friction of skin after. The hot air baths with frictions agree better with some.

In the way of medicine I would advise that 30 grains of bicarbonate of soda be taken four times a day, as far as may be from the time of meals—say an hour or more before breakfast, an hour and a half before dinner, the same time before supper, and at bedtime. If very restless, an opiate may be taken at bedtime, and the bowels kept open by the mildest means if necessary. If much debility some tonic may be needed, as moderate doses of quinin and iron before each meal. This general plan is applicable to most cases. If there are special symptoms or complications, special methods of treatment would be indicated besides. This is the best that I can advise without more precise knowledge of the case. A moderate use of buttermilk occasionally might be indulged. The diet is most important and must be persisted in. I have known some cases apparently much benefited by using working cider. A variety of meats may be indulged—beef, poultry, venison and fish as well. It would be best perhaps to put this letter into the hands of some physician—as I suppose he has some attendant—to carry out. Should he find it convenient to visit me I could be more sure of adapting remedies properly to his case. I have been thus full in my directions as the case is one of great importance, and you would not have written me, had you not wished me to give it all the attention necessary, expressing myself as fully as I profitably could.

I would like to hear from you again as to results, etc. My usual fee for a professional letter on an unusual case of this kind—varying with the means of the patient—is from five to fifteen dollars. About ten dollars in this case would be right. Should you write me again about the case I will answer your letter briefly, if necessary, without additional fee.

Yours truly, A. B. Palmer.

Ann Arbor, Nov. 2, 1865.

Kala-Azar in Madrid

Del Diestro reports what he says is the first case of kala-azar published in Madrid. The patient is a boy of 14 months, of healthy parents and antecedents. The family is living now in a healthy third-floor apartment but until the last three months they lived in a cottage with many trees in an unhygienic quarter. He comments on the unusual circumstance of kala-azar developing so far inland and at an altitude of nearly 2,000 feet and in a child who has always lived there and has not been in known contact with persons or animals who could have imported the disease, but there is a suspicious case of febrile splenomegaly in a child near the family's former home. His illustrated article is published in the *Revista Clinica de Madrid*, Sept. 30, 1914.

Medicolegal

Unlawful Prescribing and Sale of Morphin—Validity of Indictment and Statute—"Legitimate Use"

(Commonwealth vs. Gabhart (Ky.), 169 S. W. R. 514)

The Court of Appeals of Kentucky reverses a judgment which sustained a demurrer to an indictment that charged the defendant, a regularly licensed and practicing physician, with unlawfully prescribing for, procuring for, selling and dispensing morphin to another person for purpose other than legitimate use. The indictment was found under the act of 1912, entitled "An act to regulate the sale of opium or its alkaloidal salts, or their derivatives or any admixture thereof." The court says that the demurrer to the indictment was sustained on the ground that the facts therein alleged failed to charge an offense under the statute. This conclusion was based on the theory that, as the indictment failed to charge that the morphin prescribed for and sold the purchaser by the defendant was an alkaloid or derivative of opium or an admixture containing opium, and that the court could not judicially know or say that such was its character, that omission rendered the indictment fatally defective.

While, however, morphin is not named in the statute as an alkaloid, derivative, or admixture of opium, the court does not suppose there is a person of ordinary intelligence or common understanding residing in the state but has familiar knowledge of its power as a narcotic, its deadly effect as a poison, and that it is an alkaloid or derivative of opium. The word "morphin" has as well-defined a meaning as the word "whisky," and its qualities and effect are as well known to the generality of the people of the state as are those of the intoxicant known as "whisky," and manifestly it would be a work of supererogation to allege in an indictment charging one with the unlawful sale of whisky that it is a spirituous liquor or intoxicant. The validity of the indictment was not affected by its failure to state that the morphin sold by the defendant under the circumstances therein alleged was an alkaloid or derivative of opium.

Nor does the court agree with the contention that the failure of the statute to define the words "legitimate use" renders it void for uncertainty. The word "legitimate," in the statute, is not used in its original sense of lawful, but in its secondary sense of proper or warranted, as when we speak of a "legitimate conclusion" or a "legitimate argument." Morphin is sold for legitimate purposes under the statute when, under the facts, a druggist or physician, acting according to the ordinary usage of the profession and exercising ordinary care, would have made the sale. This is a question for the jury. If, on the trial, the defendant makes the defense that the sale of morphin with which he is charged in the indictment was made for a legitimate use, it will be competent for him to show by the evidence of physicians or druggists that the use for which he sold the morphin to the purchaser was a legitimate one. On the other hand, the commonwealth may also introduce evidence to show that the use was not a legitimate one. After that, the court should instruct the jury so as to enable them to determine whether or not the sale was for a legitimate use as contemplated by the statute.

Provision as to Funds of Board of Medical Examiners

(Kenehan, State Treasurer, vs. Barber et al., State Board of Medical Examiners (Colo.), 143 Pac. R. 370)

The Supreme Court of Colorado says that it would seem that the clear intent of the statute of that state is that the board of medical examiners shall deposit all its receipts with the state treasurer at the end of each month, and that it may withdraw from the treasury such sums as may be necessary to meet its fixed obligations, either contracted or performed, within a given biennial period, but that its financial affairs must be closed at the end of each of such periods, as in the case of other state officers, so that the definite amount, if any, which shall then become the property of the state may be determined and transferred to the state fund. It is clearly within the power and authority of the board to determine absolutely the question of expenditure of the funds arising within the lawful discharge of its duties, except only that, in case of any balance remaining in the custody of the treasurer at the close of any biennial period, such balance shall be transferred to the general fund of the state, and become the property of the state at that time. Clearly the board may not withdraw such funds at a time near the close of one biennial period for the purpose of again depositing the same during a succeeding biennial period to defray expenses and obligations occurring in and during such succeeding period. But the treasurer has no other power or authority in this respect than to make the transfer of such funds, and only such funds, as shall appear to be in his custody at the close of a biennial period. He is not given any authority or power to review in any manner or pass on any of the official acts of the board. The statute confers on the board exclusive powers, not only in this matter, but in all others covered by the statute creating the board of medical examiners. The members of this board are made public officials, and must be presumed to have discharged their duties honestly and within the scope of their authority. That the board may have exceeded its powers or abused its discretion, or may have wilfully violated the law and abused the trust imposed, and in so doing may have deprived the state of a sum rightfully belonging to it under the law, is not a matter for the arbitrary determination of the state treasurer, to be disposed of by an entry on his books. The members of the board are answerable for their official conduct to the chief executive of the state, and their civil or criminal liability is a question for judicial determination, on a full and complete hearing in the light of the law and the facts.

Federal Court Without Power to Order Physical Examination

(Brace et al. vs. Central Railroad Co. (U. S.), 216 Fed. R. 718)

The United States District Court in Pennsylvania says that this was a common-law action to recover damages for alleged injuries sustained by a passenger on one of the defendant's trains. It was claimed that he had suffered a fracture of the skull, resulting in permanent injuries to his brain and mind. On a refusal to have him examined by disinterested physicians to determine the state of his mind and the extent of the injury, the defendant sought to have such an examination ordered under the direction of the court. But such an action is subject to the local law concerning matters of evidence. No power to make an order for the examination of the person of the plaintiff in a case like this is to be found at common law; hence in the absence of a state law the power does not exist. The question has been variously decided in the lower courts of Pennsylvania, but it nowhere appears that it has been considered by the state supreme court. And while the decision of the Supreme Court of the United States in the Botsford Case, 141 U. S. 250, has been slightly modified by the court in the later case of Camden Sub. Ry. Co. vs. Stetson, 177 U. S. 172, in holding that a statute enacted by the state of New Jersey regulating the practice should be enforced, it still remains that short of statutory authority the courts are powerless. Wherefore the order asked for is denied.

Physicians May Testify as to Usual Effect of Nervous Shock—Test of Admissibility of Opinion Evidence

(State vs. Wilson (W. Va.), 83 S. E. R. 44)

The Supreme Court of Appeals of West Virginia holds that the testimony of physicians as experts concerning the usual and ordinary effect of the severe nervous shock incident to a rape committed on a woman, the manifestations thereof, and their duration, as bearing on her credibility as a witness and the truth of her accusations, is admissible; but, it is not in character exclusively expert, the rejection thereof is harmless error. The test of the admissibility of opinion evidence, whether expert or non-expert, is the competency or incompetency of unskilled men, constituting a jury, to form as accurate and reliable an opinion on the subject-matter of the testimony as persons having special knowledge of the subject, from their learning, professions, and experience, or their possession of such knowledge of the subject-matter as it is impossible fully and completely to communicate to the jury. Physicians are students of human anatomy, and of the qualities, characteristics, and functions of the human body and all of its parts. Their knowledge of the nervous system, its functions, strength, weakness, and the effect of influence thereon of any character is obviously more extensive and reliable than that of persons who have never studied or had occasion to observe them, in the pursuit of their vocations. Physicians come in contact with them and have them under observation almost daily. Of course, non-experts, such as men constituting a jury, would have some knowledge of the subject, and know that a shock to the nervous system would produce effect; but their knowledge as to its forms, extent, and duration is certainly not as full and complete as that of a physician of recognized ability, and the litigant is entitled to submit to the jury all the relevant material evidence he has. In the cases of non-expert witnesses, they are allowed to express their opinions on the subject-matter of their evidence when they cannot put the jury in full and complete possession of all they observed, even though they are able to lay before the jury the substance of their observations.

(Concluded from page 2069)

Treatment of Syphilis

Dr. E. H. Martin, Hot Springs, Ark.: Apart from idiosyncrasy to the drug in a few cases, a dose of salvarsan has no physiologic effect on the body temperature or intestinal elimination. Therefore we must judge that the disturbances consistently observed after its administration are due to endotoxins released from the killed organisms causing the disease. If there are many bowel movements, there is not much rise in temperature, and the converse is also true. Nausea and emesis are probably drug effects and seem to be dependent on personal idiosyncrasy.

The cure of a majority of cases of secondary syphilis may be accomplished by three intravenous doses of salvarsan. Some secondary cases have been fully sterilized of the spirochetes by one dose, as proved later by genuine reinfections; many secondary cases are cured by two doses, but to be safe three doses should be given in all cases, and if the slightest endotoxin reaction occurs after the third dose the weekly doses should be continued until it is lacking. The fact that more than three doses are frequently necessary in secondary syphilis can be explained by the probable existence of tertiary colonies which have given no symptoms. The treatment of tertiary syphilis is the same as that of the secondary stage except that here we have to repeat the doses until all of the colonies are broken up and killed. Usually from five to seven doses suffice except in cases of cerebrospinal lues, which will be considered later. Some cases of bone syphilis require more treatment, and a few cases of old tertiary ulceration of the skin are peculiarly intractable. The treatment of the fourth class of cases, tertiary infection of the cerebrospinal system, does not differ from that of other cases of syphilis except as to the greater persistence required. The final results and the degree of restoration to health will depend on the extent of damage done by the disease to nerve or brain tissue before treatment is instituted. Nothing anatomic can be restored, nor can scar tissue be removed.

Treatment of Tabes Dorsalis and Specific Paresis

Dr. Estill G. Holland, Hot Springs, Ark.: I have had six cases of tabes dorsalis and paresis which were greatly improved by intravenous injections of salvarsan.

DISCUSSION

Dr. E. G. Ballenger, Atlanta, Ga.: I have given 2,975 injections, but I have not seen secondary or other manifestations of syphilis follow in those patients who were treated before the secondary manifestations had developed.

Dr. J. K. Hall, Richmond, Va.: Syphilis ought not to be a genito-urinary disease or a disease that should come under the observation of the neurologist; it ought to be a disease for the general practitioner to discover and to treat early. In spite of the hopeful attitude of some observers, I am convinced that paresis is essentially an incurable disease.

Dr. A. J. Crowell, Charlotte, N. C.: I have used considerable salvarsanized serum in the treatment of paresis, and I think it is perfectly rational and scientific to employ this plan of treating syphilis.

Campaign Against Malaria

Dr. L. O. Howard, Washington, D. C.: The advance of civilization has increased, rather than decreased, the spread of the disease, because of the construction of ponds and stone quarries, in the still water of which the mosquito has found a favorable breeding ground. The present prophylactic measures are too general to be standardized. There are 79,000,000 acres of swamp-land country, of which 65,000,000 are in the Southern states. In addition to this vast territory of swamp acreage, there are 150,000,000 acres that need drainage.

Effects of Impounded Water in the Production of Malaria

Dr. H. R. Carter, Washington, D. C.: The great increase in impounded water in the South has resulted in a corresponding increase of mosquitoes, which, however, can be avoided if the ponds and artificial lakes can be so constructed as to be drained or be cleared of surrounding brush so as to have wind and wave action. I should suggest that all such impounded waters be placed under the control of boards of health.

Malaria Carriers and the Important Rôle They Play in Persistence and Spread of Malaria

Dr. C. C. Bass, New Orleans: Persons who are not ill and who have not been ill of malaria are the chief malaria carriers. Persons who have recovered from an attack of malaria frequently remain carriers for many months and, perhaps, years. The ideal way to deal with the situation would be to examine the blood of all persons in the house and treat the carriers. This will not be practicable in most instances, and the next best thing would be to consider all members of the household probable carriers and treat them as such. These measures carried out during the cold season are more successful because mosquitoes are not active at that time.

Malaria and Quinin

Dr. Thomas E. Wright, Monroe, La.: I have treated thirty patients with malaria of the estivo-autumnal type, with quinin intravenously. The intravenous use of quinin, in doses of 15 grains, in a dilution of from 250 to 300 c.c. of saline solution, in the hands of a careful, competent physician, is safe. The discomfort to the patient is so slight that it becomes a matter of small importance, and in this respect, when compared with quinin by mouth or hypodermically, is much to be preferred. The relief from the symptoms in malaria, so often jeopardizing life, may be attained promptly, safely and constantly by this method.

Intestinal Parasites in Adults

Dr. H. L. McNeil, Houston, Tex.: Indefinite and unexplained abdominal pains or tenderness should make one suspicious of intestinal parasites. Parasites should be suspected in all cases of chronic or subacute appendicitis. Many apparently normal men, who harbor parasites, are subject to certain indefinite complaints, diagnosed usually as indigestion, cramps, biliousness, mild diarrhea, malaria, febricula, grip, which are really symptoms of the parasitic infections. An otherwise unexplained eosinophilia is good evidence of parasitic infection, even though the parasites are not discovered at the first stool examinations; but an absence of eosinophilia does not rule out parasitic infection.

The Public Health

Dr. R. M. Cunningham, Birmingham, Ala.: All sanitary regulations among and between the states should be under the laws of the United States. Governmental direction and control is the only feasible method in which a proper regulation for the country at large can be evolved and put into execution. The federal government has jurisdiction over all matters ceded to it by the states, and all of these matters concern the common welfare. Public sentiment is necessary to procure proper laws, and to arouse public sentiment there must be education. Sanitary measures must be made political issues. So long as the people are silent, so long will the statesman fail to take the initiative. If there be a popular demand for sanitary laws, those running for office will make it one of the reasons for their election to office.

Heart Arhythmias

Dr. E. C. Thrash, Atlanta, Ga.: The principal extracardial causes of arhythmia are cortical, toxic, mechanical, reflex from pathology in other organs, and vagopathic. The treatment of arhythmias is as varied as their causes. The treatment of the ones produced by factors external to the heart itself must be based on methods which will relieve these disturbances. The neurasthenic must be relieved of his neurasthenia, the sufferer from visceral ptosis must have his condition relieved, and the mechanical disturbances which interfere with the heart's action must be diagnosed and relieved, if possible. Atropin will not only temporarily relieve these functional disorders, but the fact that it does relieve them aids one in making a diagnosis, as this drug will not relieve those of extracardial origin, but will make them worse, as it has a slightly paralytic effect on the vagus. The lesions which are intracardial must be treated by directing the attention toward the heart itself. If there are any luetic complications they should be treated. It is erroneous not to give salvarsan in this form of syphilis. Arteriosclerosis, atheroma, calcareous infiltration and toxemias play an important rôle in producing the latter lesions and they should be treated according to classic methods for handling such conditions. Digitalis is the remedy *par excellence* to restore the heart to its normal tone, and it should never be overlooked in the treatment of organic arhythmias.

Habit as an Aid to Progress.—Students of Prof. H. S. Jennings' admirable work on the "Behaviour of the Lower Organisms" will remember that his experiments have led him to the conclusion that certain Protozoa, such as *Stentor*, are able to learn by experience how to make prompt and effective responses to certain stimuli; that after they have been stimulated in the same way a number of times they make the appropriate response at once without having to go through the whole process of trial and error by which it was first attained. In other words, they are able by practice to perform a given action with less expenditure of energy. Some modification of the protoplasm must take place which renders the performance of an act the easier the oftener it has been repeated. This same is of course true in the case of the higher animals, and we express the fact most simply by saying that the animal establishes habits. From the mechanistic point of view we might say that the use of the machine renders it more perfect and better adapted for its purpose. In the present state of our knowledge I think we cannot go beyond this, but we must content ourselves with recognizing the power of profiting by experience as a fundamental property of living protoplasm.—Arthur Dendy, *Medical Journal of Australia.*

6. Destruction of Bacteria Through Action of Light.—Bazzoni summarizes his work as follows: The full radiation of certain sources containing waves below 250 microns in length will kill bacteria certainly and rapidly. Isolated ultraviolet rays of length 250 to 280 microns will not affect bacteria in one drop of water in a four-hour exposure. Isolated ultraviolet rays as short as 220 to 250 microns will kill only after several hours exposure even when the isolated radiation is of the same intensity as that contained in the rapidly destructive full radiation. The destructive power increases rapidly with decrease in wave length. The final conclusion is that the destructive effect of ultraviolet light is in some measure dependent on its association with longer radiations.

9. Viability of Typhoid Bacillus in Sour Cream.—The results of Krumwiede and Noble's experiments were as follows: The typhoid bacillus is gradually killed in sour cream by the acids produced, the rate of destruction being proportional to the degree of acidity and the number of typhoid bacilli present. The apparent disappearance of typhoid bacilli in sour cream in which the normal flora are present is due in part to the overgrowth of the typhoid bacillus by these bacteria and the difficulty of finding by their present methods the proportionately few typhoid bacilli remaining. With a moderate contamination, the typhoid bacilli are killed in about four days. With a heavy contamination or in which the initial multiplication has taken place, a longer time may be required. For this reason a clean cream which soured slowly would be more dangerous if contaminated, as an initial multiplication of the typhoid bacilli would occur and a longer time would be required to destroy the bacilli. Whether under ordinary conditions the overgrowth by the bacteria of the cream is a factor in the death of the typhoid bacilli cannot be determined by their present methods.

10. **Ice Cream Studies in Cincinnati.**—The bacterial content of ice cream is so high, says Bahlman, that studies of the cause are imperative. Cream is obviously the source of the great majority of bacteria found in ice cream. Proper pasteurization of the cream and enforcement of sanitary regulations, Bahlman claims, will reduce the bacterial count in ice cream. Pasteurization of the mixture just before freezing would bring about a still greater reduction. Pasteurized cream does not affect the taste of ice cream. Sanitation at the dairy must not be neglected, but proper refrigeration and transportation facilities in large cities are far from satisfactory. A perfect product at the source of supply may be teeming with bacteria by the time it reaches its destination, and under the present conditions pasteurization is the only remedy.

15. **Typhoid Epidemic.**—Certain striking features present themselves in relation to the epidemic studied by Kelley and Macomber which are sufficiently out of the ordinary to warrant calling particular attention to them. They are: (a) Coincidence of practically complete cessation of new cases at the end of average incubation period, following the installation of the hypochlorite plant. (b) Extent of vaccination proportionate to the total population and certain failures and complications of vaccination. (c) Efficiency of the Emergency Hospital care and low Emergency Hospital mortality. (d) The small number of secondary cases. (e) The resulting sanitary improvement in the town.

40 Diagnosis of Carcinoma. M. Kahn, New York.

32. **Ptyalism Danger Signal in Renivascular Disease.**—Profuse salivation has been encountered by Stern in three cases of renivascular disease. The increased secretion of the saliva occurred first at a period when there existed no alarming symptoms on the part of the renal apparatus, when in fact the kidneys, as evidenced by metabolic and functional tests, and the determination of urinary solids, were performing their work in the same manner as months previously. It was thus clear that the ptyalism in these cases could not have been caused by a renal insufficiency, and that the blood-vessel disease itself should be held responsible for the salivary increase.

Stern says that the excessive production of saliva may last for from two to three days, or even from eight to ten days, and may then cease entirely for one or two weeks and reappear in a lesser degree (mostly); or the secretion may soon become less profuse, but continues in larger than normal amounts. Paralytic phenomena were not present in any one of the author's three cases prior to the establishment of ptyalism, but they made their appearance in two of them within a few months after the hypersecretion had supervened. In the third case very frequent (often after each meal or every drink of water) projectile vomiting, and other reflex manifestations of cerebral involvement set in soon after the advent of ptyalism. Inasmuch as such definite aggravation of the patient's condition was in none of the cases noted *prior to the onset of the ptyalism* Stern feels justified in denominating the appearance of the latter a danger signal in the course of the vascular deterioration process. A relationship between hypersalivation and hyperhydrosis did not exist in any case. While one of the patients inclined to perspire freely, the secretion of his sweat glands was neither profuse, nor was there any direct or inverse demonstrable analogy between the two secretions. The activity of the sweat glands of the remaining two patients seemed entirely normal.

34. **Early Diagnosis of Tuberculosis.**—As an aid in the eliciting of râles over the apex Beifeld (and others to whom he has communicated the finding) has had success with what he terms the whispered-voice method. It consists in having the patient whisper in an emphatic way, repeating "One, two, three" a number of times, following which he is instructed to inspire deeply. It is a frequent observation that when other methods fail, this procedure is successful in bringing out the significant apical râles.

45. **Laboratory in the Study and Treatment of Crime.**—Three hundred and fifty cases from the first and second criminal sessions of the municipal courts, as well as a few from the domestic relations courts of Boston are analyzed by Anderson. There were 140 men and 210 women. Of the men offenders, only 16 per cent. were mental defectives, while 35 per cent., or more than twice as many, were psychopaths. Of 62 cases men arrested for drunkenness 12.9 per cent. were mental defectives, while 40.3 per cent. were constitutional psychopaths. Of 21 individuals arrested for non-support, 9.5 per cent. were mental defectives, while 66⅔ per cent. were constitutional psychopaths.

Among the female offenders there were 40.95 per cent. mental defectives. There were 17.14 per cent. constitutional psychopaths among the females. Of the women arrested there were 105 cases of drunkenness. Of these, 43.8 per cent. were mental defectives, and 27.62 per cent. constitutional psychopaths. A study of those women arrested for offences against chastity shows that 48 per cent. were mental defectives, 28 per cent. were subnormal, while only 3.84 per cent. were psychopaths. In general Anderson's studies bear out the conclusions of other investigators in regard to women offenders, that they are differentiated from non-criminals by a lack of intellectual development; that mental deficiency is the problem here. In regard to criminals as a whole, however, they contradict certain reports, for the psychopath is almost as frequent as the defective and among men recidivists is of larger magnitude.

Anderson concludes that there is a type of individual passing through the courts who form a group of as serious proportions as the feeble-minded; who furnish as much if not more trouble to the social worker and probation officer than the defective, often suspected by the layman of being insane and diagnosed occasionally by experts as suffering from psychoses, or as mental defectives, defective delinquents, emotional defectives, moral imbeciles, and what not. These individuals when studied intensively by exact methods show no real defect in the intellectual field; they give no evidence of insanity, but seem to have certain anomalies of character, a certain lack of personality—adjustments, unstable, neurotic individuals, whose adaptation is inadequate and inefficient. They easily become disordered under the influence of emotion, alcohol, etc.

46. **Some Conditions that Influence the Mortality After Prostatectomy.**—The high mortality following prostatectomy, Chute says, is unnecessary and is to be avoided in two ways: First, by getting kidneys that are not doing their work into a condition in which they are acting efficiently; second, by avoiding injury to embarrassed or susceptible kidneys at the time of operation.

47. **Magnesium Sulphate in Cerebrospinal Meningitis.**—The diagnosis in Bryant's case—cerebrospinal meningitis—was established by symptoms and lumbar puncture. A decompression operation gave immediate relief from intracranial pressure. Toxemia was combated by magnesium sulphate, water and drainage. Cure of the cerebrospinal meningitis followed in a few days. Infection of the cranial wound followed contamination of the dressings. Result, a recurrence of toxemia together with encephalitis, with death on the 190 day from time of decompression operation. Cause of death, encephalitis and toxemia, not cerebrospinal meningitis.

57 *Nitrogen Metabolism Before and After Splenectomy in Case of Pernicious Anemia. G. R. Minot, Baltimore.

53. **Production of Amebic Dysentery in Direct Inoculation Into Cecum.**—The inoculation of kittens per rectum, or the feeding of dysenteric stools rich in ameba was used by Sellards and Baetjer for the production of dysentery with widely varying degrees of success, but, in general, about 50 per cent. of infections was obtained. It has not been possible by either of these methods to propagate a strain of pathogenic ameba beyond a very limited number of passages. Inoculation of eight strains of dysentery, some of which were distinctly atypical cases, directly into the cecum, in ten kittens produced an infection in all instances. In some of the subinoculations considerable difficulty was experienced with bacterial septicemia.

Some of the factors bearing on the high rate of amebic infection following intracecal inoculations are as follows: 1. Absence of tendency to expulsion of injected material. 2. Optimum utilization of infective material and the avoidance in a large measure, of deleterious diluting agents. 3. Precision of the site of injection in the bowel. Definite evidence was obtained that the ameba are able to injure and penetrate the healthy mucosa. Unrestricted growth of bacteria in the intestine seems to be unfavorable to the entameba. A marked suppression of bacterial growth in the amebic lesion appears to be necessary for the best development of the pathogenic ameba. Animal inoculation by intracecal injection has been of assistance in the (1) propagation of a strain of ameba through a series of animals for a period of several months; (2) determination of the etiology of some obscure diarrheas; (3) study of the morphology of some atypical ameba of low virulence.

55. **Fibrinolysis in Chronic Hepatic Insufficiency.**—Specimens of blood from four cases of atrophic hepatic cirrhosis examined by Goodpasture possessed the property of completely digesting their clot within a few hours, at body temperature. Normal blood will not digest its clot for days or weeks. Dissolution of clot in the blood of cirrhosis cases, Goodpasture thinks, is due to an enzyme. Its activity is destroyed by heat, inhibited by normal serum and diminished in old plasma. The fibrinogen content of the blood in each case has been below normal. Hydremia was a constant feature. One patient exhibited a low phenoltetrachlorphthalein output. Goodpasture says that digestion of clots in vivo explains in part the hemorrhagic tendency present in these patients.

57. **Nitrogen in Case of Pernicious Anemia.**—In a case of pernicious anemia showing no improvement for three months, splenectomy was performed, after which the patient's general condition and blood-picture improved. Coincident with this improvement the urobilinogen disappeared from the urine, a more favorable nitrogen balance occurred, and a rise in per cent. of urea nitrogen, which previously had been below normal.

74 *Mental Tests of Dementia. B. Hart and C. Spearman, London.
75 *Criticism of Psychoanalysis. J. V. Haberman, New York.

74. **Mental Tests of Dementia.**—The experimental results obtained by Hart and Spearman, they say, are incompatible with the current view that dementia consists in large "defects," "gaps," "hyperfunctions" or "ataxias" in mental power, such as "disturbed association," "faulty judgment," "weak power of conception," "poverty of ideas," "loss of memory," etc. The authors believe that the method of mental tests appears to be already capable of accurately determining any person's general level of intellectual power. But before accurately measuring the impairment (especially in slight cases) one should know how great this power was in health.

75. **Criticism of Psychanalysis.**—Haberman sums up his criticism of the so-called Freudian psychanalysis as follows: Let us have some carefully and scientifically worked-out studies given to us—not "statements" erroneously called "studies" which go on without the slightest attempt to substantiate the principles employed. Let us have some wholesome and conservative investigation of such mechanisms as Verdrängung, of the carrying over of "affect" experienced in association with an incident, on concepts not originally associated with such "affect" (Hellpach makes an attempt to explain this mechanism without Freud's aid of the "unconscious"). Or again let us see to what degree personality may be laid bare by judicious anamnestic probing,

"anamnestic analysis," Haberman has called it to differentiate it from the sexuo-analysis of the Freudians, incorrectly termed psychanalysis. This is a type of inquiry always essayed to some extent by psychiatrists and neurologists, but now more carefully and thoroughly undertaken because of the renewed interest in the psyche and the psychic—a probing without the use of symbolism or interpretation or translation. Let the psychanalyst in such a procedure show how much of the past makes up mind-tendencies of the present, to what degree past "affects" can produce negative influence in the present, to what degree the sexual (as found—not interpreted) plays a part, whether the incident causing such "affects" can drop out of memory, be forgotten, and the "affect" still live on (Ranschburg, for instance, one of the foremost authorities on memory studies to-day, denies that it can), how symptoms may be explained without symbolism (for surely even the Freudist will admit that some can, by suggestion, for instance, and imitation), or if he needs his symbolism, first give some adequate proof of it, or show how it may be scientifically employed.

95 Production of Acid by Bacillus Coli Group. W. W. Browne, Providence, R. I.

79. Metabolism of Tubercle Bacilli in Simple Mediums.—A rapidly growing strain of human tubercle bacilli (597) was grown by the authors in a medium of known and very simple composition, consisting essentially of diammonium-hydrogen-phosphate, as a combined source of nitrogen and phosphorus, and dextrose, mannite, and glycerin, respectively, as sources of carbon. At the end of two weeks, 4.2 mg. of nitrogen, that is to say, 10 per cent. of the total nitrogen of the uninoculated medium, has been so changed by the growth of this organism that it cannot be recovered as ammonia. This loss of ammonia is most plausibly explained on the assumption that it has been built up into the bodies of the newly developed bacteria.

At the end of four weeks, between 40 and 50 per cent. of this lost nitrogen has reappeared in the clear medium underlying the pellicle of the tubercle bacilli in such a form that it can again be determined as ammonia. The period during which the disappearance of nitrogen from the culture fluid is the greatest corresponds with the period of maximum vegetative activity in the culture. Coincidently with the reappearance of this nitrogen, which can be detected as ammonia in solution, there are evidences of a cessation of vegetative activity. This strongly suggests that the reappearance of this ammonia is associated with a certain amount of autolysis of the bodies of the bacteria.

80. Metabolism of Lepra, Grass and Smegma Bacilli.—The authors found that the metabolism of the smegma and grass bacilli resembles that of the rapidly-growing, human tubercle bacilli, described previously, in two important particulars; neither dextrose, mannite, nor glycerin, exhibits any appreciable sparing action for the protein constituents of the broth, the amounts of ammonia produced being practically the same in these media as in plain broth; and their cultures present a gradual increase in proteolysis to a maximum which is followed by a clearly-defined recession of the metabolism indicated by a gradual decrease in the ammonia content. The lepra bacillus does not present this metabolic phenomenon. This would suggest that this bacillus was entirely distinct in its cultural relationships from the grass and smegma bacilli, which follow more closely the metabolism of the tubercle bacillus.

86. Effect of Cholesterol on Phagocytosis.—It appears from Dewey and Nuzum's experiments that cholesterol in colloidal suspension, injected into guinea-pigs and rabbits, has a depressing effect on phagocytosis. They believe that this action is probably chiefly on the leukocytes; for the opsonic index of normal serum with the washed leukocytes of an animal injected with cholesterol is lower than that of the same serum with washed normal leukocytes, and the index of the serum containing cholesterol with the washed leukocytes of the same blood shows a reduction in phagocytosis more than twice as great as that of such serum with washed normal leukocytes. The fall of the total phagocytic index, that is, of the serum of the animal injected with cholesterol acting on its own washed leukocytes, is 65 per cent. after one hour and 43 per cent. seventy-two hours after one small dose and 62 per cent. twenty-four hours after one large dose of cholesterol.

The chief difference in the results from injections of small and large amounts of cholesterol and of doses of higher and lower concentration seems to be, as far as the range of these experiments indicates, a more marked immediate effect from the large dose and from that of higher concentration. This inhibitory action of cholesterol, the authors suggests, is perhaps due to the presence of free cholesterol in the blood. Simultaneous injections of immunizing doses of streptococci with cholesterol result in an opsonic curve which is almost identical with that of the serum of an animal injected only with cholesterol. This apparent neutralizing effect of cholesterol on the formation of antibodies is marked when cholesterol is injected twenty-four hours after the animal has received the immunizing dose.

88. Effect of Iodin on Absorption.—The use of iodin and iodids in facilitating the absorption of necrotic material and organization of tuberculous and other granulation tissues, Hirsch says, has no experimental proof. The daily administration of potassium iodid does not hasten the removal of foreign substances, like tubercle bacilli, by stimulating the phagocytic properties of the endothelial cells. The presence of free iodin in such areas may influence the process only by favoring an inflammatory reaction, if the amount of iodin is sufficient, but has no effect in promoting absorption. Iodized fat-free tubercle bacilli are absorbed no faster than are the non-iodized.

90. Copper in Tuberculosis.—Corper's experiments showed that copper in simple salt form (sulphate, acetate, oleate and copper amino-acid mixture prepared from hydrolyzed egg albumin), injected intramuscularly into normal and tuberculous guinea-pigs in total amounts from 0.75 mg. up to about 19.0 mg. for about two to one hundred days, enters the animal organism and is found mainly and in largest amounts in the liver, in small amounts in the kidneys, in traces in the spleen, lungs and blood, and not at all in the tuberculous lymph-glands and pus. After cessation of injections the copper slowly but gradually decreases in amount in the liver.

Copper, in simple salt form, injected intramuscularly in guinea-pigs, in amounts varying from 2.7 to 22.1 mg. during a period of thirteen to thirty-four days, previous to (nineteen days), coincident with (two days before), or after (eleven days) infection with tubercle bacilli, has appreciable effect on the progress of the tuberculosis, as indicated by the lesions present after death.

Copper, in simple salt form fed to rabbits in amounts up to 1,380 mg. of copper, during a period of ninety-seven days, and injected (copper sulphate and copper amino-acids) intramuscularly into rabbits, in amounts up to 55.1 mg. of copper, during periods of ninety days, enters the blood and is found mainly and in largest amounts in the liver, in small amounts in the kidneys, in traces in the lungs and blood and not at all in either the tuberculous or normal eyes. Copper, in the form of copper sulphate, fed to rabbits in amounts of 1 to 2 c.c. of a 1 per cent. solution daily for up to one hundred days, begun five days before infection, and copper in simple salt form injected intramuscularly into rabbits in amounts of 12 to 42.9 mg. copper, for thirty-seven days, begun on the eleventh day after the infection, has no appreciable effect on the course of tuberculosis of the eye as indicated by the development of the disease in the eye.

Colloidal copper, prepared electrolytically by Bredig's method injected intravenously into normal and tuberculous rabbits in amounts totalling 9.6 mg. from four to twelve days, is found mainly and in largest amounts in the liver, in smaller amounts in the kidneys, in traces in the lungs and not in the normal or in the tuberculous eyes. Copper, in the form of copper amino-acid mixture, does not differ greatly in its systemic (tested in mice with the lethal dose intraperitoneally and intramuscularly, about 0.05 to 0.1 mg. copper per mouse of 10 gm.) and local (tested intracutaneously in guinea-pigs) toxicity from that of copper sulphate when equal copper contents were compared. Locally, however, a difference existed in the fact that the copper amino-acid mixture produced a hemorrhagic necrotic lesion, whereas the copper sulphate produced a single necrosis. The local nonnecrotizing concentration proved to be 0.01 per cent. copper, while 0.001 per cent. copper still produced a slight duration.

Copper, in the form of copper oleate (50 per cent.) in lanolin by inunction, and copper amino-acid mixture applied to the skins of guinea-pigs, is absorbed, but only to a slight extent and with uncertainty, as shown by the presence of small amounts of copper in the liver.

91. **Relation of Cutaneous Allergy to Anaphylaxis.**—On the ground of the conception that the anaphylactic reactions are caused by substances in close relation to the parenteral splitting of protein, Meigs' experiments speak in favor of the hypothesis that the intracutaneous reaction of the sensitized animal is not caused by the same split-products which lead to the general symptoms of anaphylaxis on the reinjection of the allergen into the blood-stream.

94. **Toxicity and Antitetanic Action of Gentian Violet.**—According to Hall and Taber gentian violet distinctly inhibits the growth of the tetanus bacillus when 1 part saturated solution is added to 10,000 of dextrose agar. In dextrose broth, however, exposure for twenty-four hours at 37 C., at this concentration, has no perceptible effect on subcultures; the cultures failed from broth containing 1 part in 100. The organisms are not destroyed, however, as can be shown by animal inoculations. One part saturated solution in ten of broth destroys the virulence of a toxic culture. At this concentration more than 99 per cent. of the toxin is destroyed by contact at 37 C. for twenty-four hours. One part in 100 has no perceptible effect. The necessity of using more than 1 per cent. saturated solution for devitalization precludes the employment of gentian violet for the practical purpose attempted through excessive soiling of laboratory ware. Within the limits tested, the toxin appears to be destroyed under practically the same conditions as the spores. Guinea-pigs and rabbits withstand considerable injections of gentian violet in 0.85 per cent. NaCl. Distilled water solutions appear to be more toxic than those in salt solution and subcutaneous injections less than intravenous injections.

104 *An Uncommon Case of Nasal Hemorrhage. J. A. Thompson, Cincinnati.

104. **Nasal Hemorrhage.**—There were two unusual features in Thompson's case. The right inferior turbinate body was all angiomatous tissue and when it started to bleed the hemorrhage could be controlled only by the complete removal of the tumor. The second unusual feature was the method of cure, a submucous resection. The septal cartilage was found to be softened and it was believed that the condition of the cartilage prevented a cure of the inflammation in the overlying mucosa.

106. **Imbedded Radium Tubes in Treatment of Cancer.**—Morton makes a further report of a case of a spindle cell sarcoma of the humerus remaining cured nine years after radium treatment. He also reports a case of primary carcinoma of the breast of the size of a large egg into which he inserted a tube containing 10 milligrams of pure radium bromid of an activity, of 1,800,000. The tube was left in place sixteen hours. A severe radium necrosis ensued, very slow to heal. Some time later on it was thought best on account of the slow healing of the wound simply to remove surgically the mammary gland involved. The patient at this date (1914) seven years later has never shown any signs of recurrence of the disease and remains in perfect health.

117. **Standing-Order Evil in Hospitals.**—The standing order is regarded by Glazebrook as a decided evil in the hospital management of operative cases, and in his opinion should be eliminated. He advises that the administration of alkaloid drugs especially morphin and atropin, commonly used in connection with operative cases, should be more

cautiously administered, and never given unless the indication for their use is positive, whereas the routine preanesthetic administration of morphin and atropin is, he says, an unsound and unscientific practice, the advantages claimed for the method not being enough to offset the risk involved.

123. **Parageusia and Its Treatment.**—As a result of a year's close questioning of patients on the subject, Reilly is convinced that persistent bad taste in the mouth is a symptom of much importance; that it is always an expression of a serious toxemia, and is frequently of great service in the early diagnosis of disease. In the early stages of chronic interstitial nephritis the patient complains of the bad taste only on arising in the morning and says that it disappears after breakfast. As the disease advances, often, but not always, it reappears later in the day, in some cases, particularly of the cardiorenal type, it reappears after exercise or at the close of the day. In one case, the ingestion of a meat meal caused a taste described as rubberlike to appear regularly two hours after eating and to persist for about two hours. In general, the prognosis seems to be worse the more constantly the taste is present.

In many instances bad taste was the only symptom the patient complained of, and Reilly suggests as a working rule that when any one, particularly a person of 45 years or upward, complains of persistent bad taste, a blood-pressure examination be made at once. This sign often precedes the appearance of other symptoms by a month or more. Next in frequency Reilly found this complaint associated with gallstones and cholecystitis. During an attack of cholelithiasis a large number of patients complain of bad taste, which is generally ascribed to coincident gastric disturbance or to the morphin given to relieve pain. In most instances, the taste is described as bitter, like gall. During the diminution of the attack, namely, after the colic has subsided while yet the pain and soreness remain, the taste is sometimes described as dry, but quite often the "gall" taste remains. In a few cases, the taste was described as being like musty eggs.

Brain, London

September, XXXVII, No. 1, pp. 1-198

1 *Clinical Aspects of Syphilis of Nervous System in Light of Wassermann Reaction and Treatment with Neosalvarsan. H. Head and E. G. Fearnsides.
2 *Comparison of Lesions of Syphilis and "Parasyphilis" Together with Evidence in Favor of Identity of these Two Conditions. J. McIntosh and P. Fildes.

1. **Syphilis in Light of Wassermann Reaction and Treatment with Neosalvarsan.**—All manifestations of syphilis of the central nervous system, according to Head and Fearnsides, are consequent on the direct activity of the *Spirochæta pallida*. The clinical picture evoked depends on the situation of this activity and on the susceptibility of the tissues. When the lesion lies mainly within the essential structures of the central nervous system, both neuroglia and the nerve elements participate in the tissue reaction. This results in the death and degeneration of certain systems of cells and fibers; to these secondary consequences may be due the greater part of the clinical manifestations. The more closely clinical signs and symptoms point to pathologic changes in the meninges and vessels, the more certainly will the disease yield to adequate treatment. On the other hand, the more nearly the clinical manifestations point to one or more foci of syphilitic activity within the parenchymatous tissue of the central nervous system, the less will they yield to the present methods of antisyphilitic treatment.

In syphilis meningovascularis the character of the Wassermann reaction in the cerebrospinal fluid depends on whether the spinal or basal meninges are affected. Should clinical evidence point to affection of the contents of the spinal canal, and occasionally when the basal meninges alone appear to be affected, the reaction is positive in the cerebrospinal fluid. When, however, the disease seems to be limited to the intracranial contents, the reaction in the cerebrospinal fluid tends to be negative or weakly positive. In cases of syphilis centralis, such as dementia paralytica, tabes dorsalis, muscular atrophy and primary optic atrophy, the Wassermann reaction in the cerebrospinal fluid is strongly positive so long as the disease is active. When, however, it has come to an end, leaving behind it a greater or less amount of irreparable degeneration, the Wassermann reaction may diminish in strength or even become negative in the cerebrospinal fluid. Under treatment with salvarsan or neosalvarsan, the Wassermann reaction in cases of meningovascular syphilis, if at first positive, will usually become negative in the cerebrospinal fluid within six months. On the other hand, the more the clinical manifestations point to syphilis centralis the less will they yield to any of the present forms of antisyphilitic treatment. No complete diagnosis or prognosis can be made until the patient has been under observation and treatment for at least six months, and the cerebrospinal fluid has been examined systematically from time to time.

Whatever the situation and nature of the lesion which is responsible for the clinical manifestations, some secondary degeneration must almost certainly result. Many of the signs and symptoms in cases of syphilitic disease of the central nervous system are therefore not amenable to any form of antisyphilitic treatment. It is, therefore, most important to make the diagnosis of syphilis early in the disease of the central nervous system, so that treatment may be employed before the advent of these secondary changes.

2. **Comparison of Lesions of Syphilis and "Parasyphilis."**—The progressive character of "parasyphilitic" lesions, McIntosh and Fildes claim, is due to a continuation of the syphilitic process in spite of treatment, and not to a progressive primary degeneration of the neurons. The degeneration passively extends to the limits of the neuron, but does not actively spread to other neurons. Treatment is ineffective in resolving the inflammation because drugs in the bloodstream are unable to pass from the capillaries into the nervous substance in order to destroy the spirochetes. If by some method salvarsan succeeds in penetrating into the brain or cord, it produces such toxic symptoms as make its use impossible.

12 Operative Treatment of Abdominal Aneurysm. W. I. de Courcy Wheeler.

4. **Present Knowledge of Thyroid.**—A 4-year-old typical cretin was treated with thyroid extract for about three years without intermission. He came under Mamourian's care in January, 1910, and he continued the treatment for over six months, prescribing 20 grains of the dry extract per day. Neither his physical nor mental condition underwent any appreciable change. Mamourian then decided to try grafting. He had a sheep killed in the hospital while the patient was being anesthetized, removed the thyroid, placed it in hot saline and after incising it in several places planted it into the child's omentum, which was scarified with a needle. The patient made wonderful headway. Four years after the operation the boy has entirely lost his repulsive countenance, and looks pleasant and intelligent. He can read and write, tell the time and recognize coinage. He has grown to the extent of 10 inches in four years. Since the operation he has very occasionally had a 5-grain tablet owing to a stutter which he develops at times, and which, according to the observation of the boy's mother, completely disappears when a small dose of extract is given.

6. **Blood-Platelets in Treatment of Disease.**—Though good results are obtained from small doses of platelets and their plasma, such as from 1 to 5 c.c., Dimond has in particular cases, according to the indications, by means of 20 c.c. Record syringes, administered as much as 30 to 40 c.c. directly into the connective tissues under the skin between the shoulder blades. During an experience of many hundreds of injections, varying from 1 c.c. to 40 c.c., he has never yet seen any untoward result apart from a slight reddening of the skin for a few centimeters around the puncture, which clears up in from twenty-four to thirty-six hours. The patients have never complained of any pain as an immediate or after result of the injections, and in the majority of cases the hyperemia of the skin is simply accompanied by a slight sensation of itching.

When vaccines are administered either with the platelets or after sensitization by means of the platelets and their plasma, more definite local signs are the result, but never so marked or so intense as when the vaccine alone is injected. Having treated with platelets a large number of acute and chronic pulmonary conditions, as well as numerous cases of the secondary infection in phthisis, Dimond has found that for the organisms noted below the most suitable time for isolation of the platelets is, as a rule, as follows: *Diplococcus pneumoniae*, platelets withdrawn fifth day after injection. *Micrococcus catarrhalis*, platelets withdrawn third day after injection. Friedlander's bacillus platelets, withdrawn eighth day after injection. *Bacillus influenzae*, platelets withdrawn second day after injection. *Streptococcus pyogenes*, platelets withdrawn third day after injection. *Bacillus septus*, platelets withdrawn sixth day after injection. *Bacillus pertussis*, platelets withdrawn third day after injection. Regular estimations of the opsonic index in certain of these cases have shown that when the platelets are withdrawn after the above interval following the vaccine injection the best immunizing response is obtained.

13. **Cases Treated with Bêraneck's Tuberculin.**—The first case cited by Fleming was one in which there were innumerable caseous cervical glands, so extensive as to preclude the possibility of their being removed by operation in the usual way, and Roentgen-ray examination demonstrated that the glands extended into the mediastinum. The second case was a tuberculous pleurisy with effusion, which had persistently resisted other treatment, and in which the swinging temperature, rising sometimes to 100 F., sometimes as high as 101 F., fell at once after the first dose of tuberculin, and did not rise again above normal. The third case was that of a boy aged 13½, suffering from tuberculous glands in the abdomen, attended by a great deal of abdominal discomfort. He had no pyrexia, but his increase in weight, and the general improvement in the condition of the abdomen which followed treatment, were alike remarkable.

The fourth case is interesting because, although under the effect of tuberculin, the temperature suddenly ceased to swing; there was no improvement in the patient's condition as regards the tuberculous lesion. While under tuberculin treatment, the boy started what was proved pathologically to be an extensive miliary tuberculosis and died of tuberculous meningitis. Small doses of Béraneck's tuberculin, given during the period when the meningitic symptoms were most marked, did not have any effect either in reducing temperature or in alleviating symptoms.

33 Action of Drugs on Plants. J. C. Bose.

32. **Accessory Spleen Causing Acute Attacks of Abdominal Pain.**—In the case which Alexander and Romanes observed the patient was a young woman aged 25, who three years previously had had her right kidney removed for calculous pyonephrosis. A year previously to her admission to the hospital she was suffering from an attack of tonsillitis, and while her medical attendant was treating her for that condition she complained of abdominal pain. Alexander, who saw her at that time, discovered a mass about the size of a golf ball in the left upper quadrant of the abdomen. This mass could be freely moved about all over the upper abdomen and was somewhat tender to touch. The only other clinical facts of note were a greatly enlarged left kidney, possibly a compensatory hypertrophy, and a considerable degree of albuminuria. A few days later another examination was made, and this time the lump could not be felt until the patient sat up in bed, when it was easily palpated. She was sent to the surgeon who had previously removed her kidney, but owing to her general health being below par, he was unwilling to operate. She returned home and improved in general health, but was subject to frequent attacks of pain of a dragging nature in the upper abdomen, this pain having no relation to the taking of food. The pain was usually rendered worse when the patient stooped, and was unaccompanied by other symptoms. These attacks of pain occurred

almost daily, coming on suddenly, lasting for one or two hours, then passing off and leaving her quite well.

In August, 1912, with the exception of the enlargement of the left kidney, nothing abnormal was detected on examination. The spleen was normal in size. Her general health was good and the amount of albumin in the urine very small. The tentative diagnosis of mesenteric or omental cyst was made, and as the patient said that the pain was exceedingly severe when it occurred and that it made her miserable, under a general anesthetic an incision was made through the upper part of the left rectus muscle. The viscera appeared normal and no trace of any tumor could be found till the hand was passed up under the diaphragm on the left side and a rounded mass was felt. This proved to be an accessory spleen about the size of a small tangerine orange situated at the lowest part of the great omentum. There were several large vessels running toward it. The omentum was ligated and the splenculus, which was entirely surrounded by omentum, was removed. The stump of the omentum was carefully stitched to prevent adhesions forming and the abdomen closed. No other accessory spleens were seen. Convalescence was uninterrupted and the patient had no recurrence of symptoms. Microscopically, its structure resembled that of the spleen, except that the lymphoid follicles were not so well developed and that there was considerable fibrosis of the whole organ with recent and old hemorrhages. The authors regard that cause of the pain to have been congestion of the viscus from torsion of the omentum obstructing the return of the blood-flow. There was no necrosis visible and there had been apparently no arterial obstruction.

45. **Transplantation of Nerve.**—In the case reported by Cahen a gap of 12 cm. was left in the ulnar nerve after removal of a neurofibroma. The patient was a woman of 48 and the gap was bridged with the medial cutaneous nerve of the forearm. It was easily separated from the ulnar nerve in front of the axillary vein, and divided on a level with the peripheral stump of the ulnar nerve. The central stump of the cutaneous was then joined by a perineural suture to the peripheral end of the ulnar nerve. The central end of the ulnar nerve was then sutured to the trunk of the cutaneous nerve. The functional use of the nerve became restored surprisingly soon. By the fifth week the interossei muscles were functioning, and within six months the hand was being used practically normally. Sensation returned on the ulnar side of the fourth finger. Light pressure on the little finger still causes a slight tingling to run up the forearm.

47. **Luetin in Differentiation of Surgical Processes.**—A positive reaction testifies with practical certainty that the affection in question is of syphilitic origin, according to the experiences related in this article. If there is no pronounced reaction, the test should be repeated a week or ten days later; it may then prove positive. Negative findings by no means exclude syphilis. The reaction is more constantly positive in the third phase of syphilis, and especially when there are manifest surgical lesions. In these conditions the luetin test was found more reliable than the Wassermann.

48. **Splenectomy in Jaundice from Excessive Destruction of Blood.**—Graf comments on the familial character of this disease, and the absence of detectable bile pigment in the urine while it is present in the blood. The second generation feels the effects, generally, more severely than the first generation known to be affected. Some are born with the jaundiced tint; others develop it later. Hemolytic jaundice differs from Banti's disease chiefly by its familial character and the exceptional fragility of the red corpuscles. In Banti's disease, further, the jaundice stage is comparatively brief. Graf reports the case of a family with thirteen living children in which the father and six of the seven younger children present the typical syndrome of hemolytic icterus. The others have escaped it, and the jaundice was never very pronounced and in some has retrogressed. The enlargement of the spleen preceded the jaundice by several months, and the general health fluctuated with the size of the spleen. The two girls who seemed most seriously affected were treated by splenectomy with great benefit. The spleen was removed also from a man of 38 with typical hemolytic jaundice. The family history in this case was not known, but the jaundice had been noticed for nine years. The results a year after the splenectomy in these cases confirm the advantages of this procedure in hemolytic jaundice in adults. In the girl of 12 the reds have increased until they now number almost seven millions, and time alone will tell how the child is going to bear this polycythemia. Splenectomy therefore should not be advised for a child unless forced by severe disturbances. In the above-mentioned family the physical development of one youth of 17 was below par, and in the last few months he has had pneumonia and articular rheumatism. On this account splenectomy was advised, but the family refused.

49. **Mediastinal Dermoids.**—Pohl summarizes six additional cases found in the literature since Dangschat's compilation in 1903. The list includes Ceelen's case in which cancer had developed in the dermoid tumor. Pohl then reports the fifty-second case. It was a typical teratoma found in the anterior mediastinum of an otherwise healthy girl of 7. She died about a year after a contusion of the chest during play, followed by various respiration and heart disturbances from the injury to the teratoma.

50. **Mechanical Predisposition to Apical Disease.**—Iwasaki's extensive experimental research failed to confirm the alleged anatomic and pathologic bases on which Freund founded his operation of chondrectomy and Bacmeister his induced stenosis of the upper aperture.

52. **Lingual Goiter.**—Asch removed a small tumor from the base of the tongue which the patient, a healthy woman of 28 with three healthy children, first noticed two weeks before. It caused no disturbance except some interference with breathing as she lay in bed. What seemed to be the thyroid gland could be palpated deep in the neck, so no danger was anticipated from removal of this tumor even if it proved an accessory thyroid gland. The microscope revealed that the tumor was made up of both thyroid and parathyroid tissue. The woman felt well for a fortnight and then developed postoperative tetany and myxedema in a pronounced form, and by the end of six months she presented typical cachexia thyreopriva and parathyreopriva. She failed to take the thyroid treatment that had been advised, but the disturbances gradually subsided spontaneously. At present, four years since the operation, there are no symptoms except a slight myxedematous condition. The literature on lingual goiter is reviewed, with 133 bibliographic references. Among the 95 cases on record are 35 in which signs of thyroid insufficiency had been noticed before the operation (21) or necropsy (14). Only 12 per cent. of the total cases were in males. These tumors are always on the median line of the tongue, and generally fluctuate in size. In one case iodin treatment caused the tumor to increase in size while the general health suffered. Palpation of the thyroid region is not always very reliable, and in Asch's case had probably given misleading findings. In 9 per cent. of the total 95 cases of lingual struma, myxedema followed its removal. It would be better not to remove the whole of the tumor in case of doubt. In 4 cases another operation was required later; in a few other cases the tumor returned but subsided spontaneously later.

54 *Dysentery. G. Singer.
55 *Symptoms and Treatment of Tetanus. F. Blumenthal.
56 Exanthematous Typhus. (Flecktyphus.) A. Frisch.
57 *Genital Hemorrhage in Newly Born Girl Babies; Ten Cases. (Genitalblutungen neugeborener Mädchen.) E. Zacharias.
58 Treatment of Arteriosclerosis and Obesity. C. H. Wedekind.
59 *Action of Epinephrin. (Zur Frage der Adrenalinwirkung.) J. Löwy.

54. **Dysentery.**—In the course of this discussion of the present status of dysentery Singer emphasizes that it must be managed on surgical principles. That is, we must appreciate that there is a large area of pathologic surface, and that the task is to keep this surface well drained and prevent accumulation of secretions at any point. The diarrhea is Nature's effort to accomplish all this, and we must aid this by copious flushing out of the bowel. He uses a soft two-way tube for this, and can thus flush the bowel with three or more liters, without discommoding the patient, until the fluid comes away clear. He commends bolus alba or charcoal as an important aid. In conclusion, he warns that the bacilli are liable to settle down and hibernate, as it were, for years. This is probably the true cause of chronic ulcerative colitis in some cases.

55. **Tetanus.**—Blumenthal, in commenting on the importance of an early diagnosis of tetanus, says that pains and twitching in the muscles around a wound liable to be infected with tetanus germs should give the alarm at once and call for preventive injection of antitetanus serum. These slight pains in the region are usually ascribed to rheumatism. We must constantly be impressed with the fact that trismus is by no means the first sign of tetanus, although it is of course the first unequivocal sign.

57. **Genital Hemorrhage in the Newly Born.**—Zacharias reviews the literature on this subject and reports ten cases from Zweifel's service at Leipzig. The hemorrhage does not seem to have any practical importance, and it subsides spontaneously after a day or so, although in some of the cases on record there was scant oozing of blood from the vagina for four to eight days. No symptoms accompanied the genital hemorrhage. Halban ascribes it to hyperemia of the uterus induced by the action of some hormone from the placenta, but Zacharias remarks that it must be more than a casual coincidence that his ten cases were all in unusually large children. At any rate, he adds, the unusual size of the child predisposes to the phenomenon. These ten cases represented 2.5 per cent. of the 400 girl babies systematically examined to detect the tendency.

59. **Dangerous Action of Epinephrin in Addison's Disease.**—In Löwy's case of advanced Addison's disease an intravenous injection of epinephrin caused sweating over the entire body and then sudden arrest of both the heart and the respiration. Only after half an hour's vigorous artificial respiration was the patient revived. In another case there were signs merely of irritation of the left sympathetic. An intravenous injection of epinephrin was followed by intense tremor and pallor, and the left side of the face alone was bedewed with sweat.

74 Orthopedics for the Wounded. (Die Orthopadie im Kriege.) F. Lange. Commenced in No. 42.

62. **Cardiac Asthma in a Child.**—As arteriosclerosis is so rare in children, cardiac asthma is correspondingly rare, but Rohmer reports a typical case in a girl of 6 subject to recurring articular rheumatism. There was also heart disease and a tendency to dropsy when the child was first seen. The failing compensation was restored by suitable treatment and the ascites was absorbed. The fifth week, however, severe dyspnea developed like a bolt from a clear sky; the contrast was striking between the extreme difficulty in breathing and the negative physical findings. After a few days pulmonary edema ensued, speedily fatal. The necropsy findings confirmed the explanation of the syndrome as true cardiac asthma.

63. **Restriction of Fluids in Treatment of Edema Not Due to Heart or Kidney Disease.**—Nonnenbruch's experience has confirmed the assumption that the edema with kidney disease is the result of factors outside the kidneys. In a recent case of lymphatic leukemia in a man of 53 with edema in the left leg for six months and of both for three weeks, he kept down the intake of fluids. The output of water was increased materially by not allowing the patient more than from 700 to 1,100 c.c. of fluids during the twenty-four hours, and finally not over 600 c.c. With this the urine totaled systematically from 1,020 c.c. to 1,500 c.c. The edema subsided and the patient felt immeasurably relieved and was able to walk once more. In a case of pleurisy with effusion in a man of 25 similar benefit followed reduction of the intake of fluid to 500 or 600 c.c.; the amount of urine increased and the specific gravity ran up from 1.020 to 1.028. The area of dulness grew smaller and there was considerable subjective relief. In two other cases the benefit was also striking when the intake of fluids was restricted to 500 c.c. or less. In one patient the edema accompanied a cancer in the stomach; the other patient, a woman of 43, had an ovarian cyst, extreme ascites and pleurisy. Twelve liters of ascitic fluid were

drawn and the intake of fluids restricted for two weeks to about 400 c.c. When more was taken, the weight rapidly increased and was brought down to normal only by keeping the intake at 200 or 300 c.c. for several days. This patient died soon after of pulmonary edema. These cases amply confirm the beneficial influence of restricting the intake of fluids in dropsy from any cause.

64. **Roentgen Treatment of Exophthalmic Goiter.**—Sielmann has given twenty-one Basedow patients systematic Roentgen treatment in the last five years. The total duration of treatment was from six weeks to six months, and he never allowed the exposures to reach the point of inducing a dermatitis. His experience was so favorable that he urges this as the routine method of treatment after failure of medical measures. If this fails, then an operation should be considered. It may prove useful likewise to supplement operative treatment if this does not realize a complete cure. Only one of his patients failed to show benefit from the Roentgen treatment and required an operation. One patient was a young man with palpitations for a period of eight years, developing into pronounced typical Basedow's disease, was remarkably improved by four exposures, and by the end of three months, interspersed with three weeks' pauses, he was practically cured. The neck was 4 cm. smaller in circumference and the pulse, formerly 120 or 160, was permanently 80 and the exophthalmos and tremor had entirely disappeared. Another case teaches that an operation on the thyroid gland is not always a complete cure. The improvement for a few months after the Roentgen treatment yielded to a stormy recurrence of the syndrome and operative treatment was applied. This was followed by apparently a complete cure for a year, but then the whole syndrome returned again, but was banished anew by a few Roentgen exposures. Another lesson from this case is that the ovaries, the pituitary body or other glands evidently cooperate in bringing on Basedow's disease, and thyroidectomy does not remove all the cause.

68. **Tetanus.**—Voelcker reports encouraging success with a combination of antitetanus serum, subcutaneous injection of 5 c.c. of a 2 per cent. solution of phenol, plus local cauterization of the wound with concentrated phenol. This does not produce an eschar at once, to impede its action on the tissues, so it burrows deep and effectually sterilizes. He reports four cases of tetanus after shrapnel wounds in which this method of treatment was successfully applied. The trismus came on from the ninth to the fourteenth day after the injury. He gave the subcutaneous injections once or twice a day at first, increasing to five or six a day.——Eunike reports ten cases of tetanus among the 3,000 wounded in his charge at Ludwigshafen. The incubation was from nine to twenty-one days, and five of the men died. He warns that the early symptoms are liable to be ascribed to rheumatism or be disregarded, and thus precious time is lost.

72. **Losses in the War.**—Krecke's text is the necessity for economy in dressings for wounds, and he suggests various fiber-woven materials that might be used instead of cotton for dressings. To emphasize the need for economy, he remarks that losses up to 50 per cent. must be reckoned with in this war. In the Franco-Prussian war the losses averaged 18 per cent.; in the Manchurian campaign the Russian loss was 29 per cent. and the Japanese 40.9 per cent., but in the present war, he continues, "With 2,000,000 fighting, we must look for losses of 1,000,000. How large a proportion of this will be composed of wounded we have no means of estimating, but it is certainly not exaggerating to say that we can reckon with a half million wounded in the course of the first year of the war."

84 Care of the Wounded. (Verwundetenfürsorge im Kriege.) v. Eiselsberg. Commenced in No. 43.

75. **Chronic Veronal Poisoning.**—Glaser summarizes from the literature nine cases of chronic veronal poisoning and adds a tenth case to the list. The drug had been prescribed for a temporary condition and the patient had continued its use for several months. Even when the single doses are small, the continued use in this way is liable to entail serious symptoms. The central nervous system is affected by it, and predominantly the cerebellum and the vestibular portion of the cochlea. The gastro-intestinal tract and vascular apparatus do *not* seem to be affected except as the drug depresses the action of the bowels and kidneys. This, with the euphoria and the habituation to small doses, tend to magnify the toxic influence of the veronal. The experiences related warn of the necessity for care in prescribing veronal for patients with a tendency to nervous or mental asthenia, and in any event to see that the drug is not taken continuously.

76. **Psychic Changes After Resuscitation of the Hanged.**—This number of the *Wochenschrift* is dedicated to von Wagner in honor of the twenty-fifth anniversary of his incumbency of the chair of nervous and mental diseases at the University of Vienna. He published about that time two cases in which women had been resuscitated after apparent death by hanging. Herschmann here reviews the similar cases on record and describes four unpublished cases. The upset of the circulation in the brain by the hanging causes a reactional functional hyperemia with concomitant physical-chemical phenomena which, in a number of cases, either completely cured a preceding psychic affection or aggravated it to complete mania. Redlich has witnessed a similar complete cure of extreme melancholia after recovery from a suicidal dose (3 or 4 gm.) of tincture of opium. Pötzl has observed a similar transformation after sunstroke in several instances.

81. **Etiology of Nervous and Mental Disease.**—Redlich compares 6,000 cases from his private practice with the statistics from a number of hospitals in Vienna and Berlin. In 14 per cent. of his 6,000 private cases syphilis could be incriminated. Multiple sclerosis was much more frequent in women than in men, while tabes affected 364 men to only 37 women. General paresis affected 39.7 of the men and only 4.4 of the women among his 890 patients with mental affections. In the hospital patients there was not this discrepancy, the figures being here 23.7 per cent. of the men and 11 per cent. of the women. The large percentage of syphilogenous affections and the evidence of the predominance of arteriosclerosis of the cerebral vessels, are interesting facts demonstrated in his private practice as compared with the hospital patients. In his 59 exophthalmic goiter cases, the women outnumbered the men 2.2 to 1, but of the 145 neurasthenics, there were 100 men to each 41.7 women.

83. **Tetany of Gastric Origin.**—Wexberg's patient was a woman of 56 who since the age of 37 had had more or less "stomach trouble" and at 48 attacks of tetany came on and recurred during the following eight years, at intervals of from three to six weeks. Wexberg's diagnosis was true tetany of gastric origin, and he gave the woman hydrochloric acid and pepsin to supplement the deficient gastric digestion, the test breakfast having shown apparently total lack of acid and pepsin in the stomach content. This treatment restored clinical conditions to normal; all the stomach symptoms subsided and with them the signs of tetany, including Trousseau's phenomenon. For the first time in eight years there have been no spasms for more than two months to date. The literature on the subject of gastric tetany is reviewed.

86. Reviewed in The Journal, Oct. 31, 1914, p. 1615.

88. **Classification of Uremia.**—Reiss presents evidence to prove that uremia occurs in three principal types, with mixed forms. The first type, asthenic uremia, is characterized by drowsiness and apathy, physical fatigue and liability to sudden death from heart failure. The elimination of salt, nitrogen, etc., by the kidneys is defective. In the blood the osmotic pressure and the residual nitrogen are abnormally high. The second type is that with a tendency to convulsions and paralysis of speech and limbs. The external secretion of the kidneys is normal and likewise the blood findings in this form of uremia. The third type is characterized by psychic disturbances, confusion, hallucinations, visual and other delusions and profound coma. These conditions are generally transient. With this type also there does not seem to be any retention of normal waste products, but the arteries of the brain show signs of sclerosis in these cases, and this possibly favors the trouble. Mixed forms with one or the other of these types predominating are most common. Pure examples of the first and third types are comparatively rare. The trouble in uremia seems to be mainly an inability to dilute properly the juices and fluids in the body. The normal relations between the water and the dissolved substances are upset. The blood-serum shows the albumin content constantly within or above normal range, even when by intake of large amounts of fluid and venesection efforts are being made to dilute it.

101 The Normal Bladder and Its Sphincters; Changes Following Suprapubic Prostatectomy. A. Hyman (N. Y.).

96. **Wandering Kidney.**—This long article from Küttner's service at Breslau is based on 48 cases. Operative treatment was applied in 25; on both sides in 4. There was ptosis of other organs in 12 and trauma was incriminated in 12; 22 of the 40 women had borne children and there was intermittent hydronephrosis in 9 cases, and 18 of the patients had had attacks of local pain. One patient died within a year of uremia and one succumbed to hemophilic hemorrhage after the operation, and another was saved only by nephrectomy. Recent data from 16 of the 19 nephrectomized patients show that 4 were cured, 5 improved, 5 unimproved and 2 have died; from 8 of the 17 given conservative treatment, only 3 are cured and 2 improved; 3 were not benefited, and one of the improved has to wear a bandage. Küttner suspends the kidney from the twelfth rib, passing one or more suture threads through the parenchyma of the superior pole and suturing the capsule with silk to adjacent muscle or fascia; sometimes one drain; bed-rest for eighteen or twenty days.

98. **Cancer of the Ureter.**—From a woman of 54 Chiari successfully removed 15 cm. of the left ureter containing a papillary cancer, the eighth he has found on record. He compares his case with others of cancer of the ureter, the literature showing seventeen cases of primary malignant disease in the ureter. The diagnosis in his case was rendered practically certain by catheterization of the ureter, showing the bleeding obstruction.

Zentralblatt für Chirurgie, Leipsic

102 *Economy in Dressings. (Ueber Sparsamkeit beim Gebrauch der Verbandstoffe.) F. Franke.

102. **Economy with Dressings.**—Franke protests against too frequent change of dressings, and says that the dressing material often is not utilized to the utmost. Unless there is danger that the scar may be disfiguring, he does not change the dressings as early as some do, seldom before the ninth day after amputation of the breast, for example, which he always drains now since he had disagreeable experiences in a few cases with retention of blood. He insists on having the dressings applied in his service in such a way that they can be unwound and placed to soak till next day in the already used lye in the laundry. Then they are washed in fresh lye, rinsed, dried and sterilized. By this means they can be used over again, six or seven times or more. Gauze sponges are used over again in the same way—eight layers are overcast to make a sponge; when they grow too ravelly, a number of them are wrapped in a square of mull and used for a dressing pad. The outer bandage can be made of thicker mull or cambric and lasts indefinitely. The dressings can thus be utilized to the last scrap, and end by doing good service in the form of sterilized lint. He has never had any harm result from this economy in dressings, no infection among the washerwomen. The ironing is done by convalescents.

117. **Stercobilin in the Stools.**—Gastaldi remarks that exact findings are not attainable even with the most complicated usual tests for determination of bile pigment in the feces, while the simple method he uses is accurate enough for practical purposes. He dissolves 0.01 c.c. from the twenty-four hours stool in 50 c.c. of 95 per cent. alcohol and adds 1 c.c. of Obermeyer's reagent, stirring it well for twenty minutes. It is then filtered, evaporated down to 10 c.c. and the Nencki reagent is added until there is a pronounced green fluorescence. The amount of dilution required for this is the quantitative index. At the same time he examines the urine in the same way, stirring 0.01 c.c. from the twenty-four hours urine into 10 c.c. of chloroform; sets it aside to settle, decants the urine, and adds 5 or 6 drops of fuming nitric acid. He then adds alcohol to the chloroform extract thus obtained until the fluid becomes limpid; evaporates down to 10 c.c. and then dilutes with the Nencki reagent until the green fluorescence develops. He tabulates the findings with these tests applied parallel to both urine and stool. In normal conditions the average dilution required is 1:350 and never more than 1:500. In cirrhosis of the liver, fluorescence was apparent even with a dilution of 1:1,300 in one case and the range in five cases was from 500 to 1,300. In seven cases of pernicious anemia the range was from 1:1,000 to 1:4,250. (The Obermeyer reagent is the familiar 2 per thousand solution of ferric chlorid in concentrated hydrochloric acid. By the Nencki reagent Gastaldi probably means the test for indol with nitric acid plus a little nitrous acid.)

129 *Prognosis in Pneumococcus Meningitis. A. R. Krever.
130 *The Chemical Action of Chymosin. V. M. Sudakova. Commenced in No. 25.

126. **Serodiagnosis.**—Tara and Kochneva compared the dialysis and the optic methods for the Abderhalden test, their findings showing that placenta tissue is not digested by the serum of normal persons, but is digested by that of nephritics. The serum of a pregnant woman digests placenta, carcinoma and lung tissue. The serum in progressive paralysis digests brain tissue, which is not digested by serum from patients with functional psychoses or neuroses. Placenta extract digests placenta and lung tissue, but not that of cancer.

129. **Prognosis in Pneumococcus Meningitis.**—Krever distinguishes two forms of pneumococcus meningitis which differ according to the place of origin, and which give a different prognosis. One form is a pneumococcus meningitis as the result or complication of some other pneumococcus infection, such as croupous pneumonia, otitis media, sinusitis, or endocarditis, etc. This form gives a decidedly unfavorable prognosis. The other form of meningitis is caused by pneumococcus infection from the nasopharynx, when the micro-organisms invade the blood. This form has a comparatively favorable prognosis. The difference in the prognosis is due, Krever thinks, to the varying virulence of the virus which is more active in the former type, leading to a purulent meningitis which usually proves fatal. Coming from the nasopharynx, the virulence of the micro-organisms is somewhat attenuated, causing only a serofibrinous or hemorrhagic inflammation with a better outlook.

130. **The Chemical Action of the Milk-Curdling Ferment of the Gastric Juice.**—This ferment, chymosin, commonly occurs together with the proteolytic ferment, and produces a sediment from solutions of peptonized products. Sudakova studied the chemistry of this ferment experimentally and came to the following conclusions: During the action of chymosin on solutions of peptones there occurs a change of their ability to bind acids and alkalies. These changes depend on the degree of acidity of the medium. Greater acidity of the medium (0.3 per cent.) diminishes the binding ability of the peptones; a lesser acidity (0.04 per cent. and 0.14 per cent.) increases same. The amount of the ferment apparently plays some rôle, but there does not seem to be any direct correlation between the amount of the ferment and the change in the properties of the proteins to bind acids and alkalies.

139 *Gummatous Myocarditis. (Gummøs hjertesyfilis.) F. Harbitz.

139. **Gummatous Myocarditis.**—In Harbitz' case a man of 38 who had contracted syphilis fifteen years before, suddenly developed dyspnea and cyanosis and died the fourth day. Necropsy disclosed adherent pericardium and total obstruction by gummas of the superior vena cava for a distance of 1 cm. The lumen was completely obliterated. In this segment and also in the wall of the right auricle and left ventricle there were several gummatous formations. There were also syphilitic changes in the small branches of the coronary artery, in the pleura and the adjacent lung tissue. This is the third case of gumma in the myocardium ever encountered at the Pathologic Institute at Christiania. Syphilis as a direct cause of death, as in this case, is comparatively rare.

THE SOCIAL STATUS OF MEDICAL PRACTICE*

E. P. LYON
Dean of the Medical School, University of Minnesota
MINNEAPOLIS

This is a significant occasion. Here sit the senior class of St. Louis University, School of Medicine, for the last lecture which they as students will ever listen to. Here are gathered the faculty to lend emphasis to this last lecture. Here stand I who have taught these students and now am chosen to speak last for this faculty to this class. Here on the table are rolls of parchment—the visible tokens of years of toil, of a task accomplished and of this strong, old university's stamp of approval. You, my boys, will presently come up here to receive these diplomas. You will cease to be students in the technical sense. You will become Doctors of Medicine. It is a good time for "balancing the books," for inventory, for forward-looking.

From the army of men of your age you have been picked out. You are a favored few of a large social group. You have received the discipline of a useful and honorable profession. You have been prepared for work in the world. You may think you have done this yourselves, but you have not. Your ancestors who passed on to you choice gifts of heredity have done it. Your fathers and your mothers who denied themselves for you have done it. The race of doctors from the nameless founder of medicine far back in the dark of prehistoric time has made it possible for you to sit here. Large-hearted philanthropy has done it. Wise statesmanship has done it. Broad-minded municipal spirit has done it. The mighty power of human society has done it. Admitting that you have done your share and done it well, the question nevertheless confronts you, "How will you repay these priceless gifts which humanity has conferred on you?"

Now I warn you that I am not going to tell you how to repay. I am not going to lecture you on your duties. This is not going to be a sermon. You are old enough to decide for yourselves. The sentiment I am going to set before you is this from Thomas Huxley: "Learn what is true in order to do what is right."

Knowing What is True: That is where the shoe pinches. Life is very complex. The world is full of people. Interests are multiple and conflicting. Vision is partial and fleeting. Do the best you may, nevertheless the life of each of you is bound to be, in a measure, "A Doctor's Dilemma." If you succeed here, you must fail there. If you master this, you must let that other go. If you save this man's life, you must leave that other perhaps to die.

No one can deliver you from these alternatives. You must make your own judgments. They are what make life worth while. You must stiffen your backbone and carry your own load of responsibility. You must for your own selves "learn what is true in order to do what is right." This address is intended to direct your eyes toward some of the great problems concerning which you must learn the truth, if you are to lay out your lives as physicians along broad and satisfying lines; if you are to be "doctors" in the fullest sense.

EGOISM AND ALTRUISM

At the start I wish to remind you of the two motives which knowingly or not will rule the life of every one of you. First is the egoistic or individualistic motive. This begins with the fact that each one of us is a unit, a single separate animal. Each must live his own life. Each must breathe for himself, eat for himself, sleep for himself, think for himself, enjoy for himself, be sick for himself, die for himself. We cannot get around or deputize these inexorable necessities. Consequently the egoistic motive from the birth of humanity has always been very powerful. It says: "Push forward. Overcome obstacles. Drive off opposition. Overwhelm competitors. Grasp and do not let go. Take wherever ye find. Grow fat, for it is your right. Live your own life fully, for it is all you have. Let others look out for themselves." Thus speaks individualism. Its battle-cry is the Survival of the Strongest. Its prototype is the Superman.

Over against this is the altruistic or group motive. It begins with the fact that each one of us had human progenitors. Our mothers bore us into the world. Our fathers protected us in early life. But all humanity has done in a measure what our fathers and mothers have done. We are members of a great community. We have inherited and must bequeath. The race is more than the individual. We *cannot* live for ourselves alone. We ought *not* to live for ourselves alone. Hence arises the altruistic philosophy, and it says, "Do unto others as ye would they should do unto you." Its battle-cry is Human Brotherhood. Its prototype is Jesus of Nazareth.

Thus are and thus speak the two great motives, egoism and altruism. They seem antagonistic, unlike, far apart as the poles. Yet from a practical point of view we see both acting together in every human being. No man can live absolutely by or for himself. The hermit hunter of the mountains comes down for bullets and gunpowder. The all-conquering Napoleon must make dukes and kings of his generals. On the other hand, no man can live wholly for others. In the first place he cannot get around the imperative necessities of his own body. He must provide for himself. The merchant who gives away his goods soon has no goods to give. The missionary who goes unprotected among cannibals is eaten. To come nearer home, the doctor who does not charge for service will not long be able to serve. It amounts in the end to this: A reasonable regard for self is indispensable that we may serve others. A reasonable service for others is indispensable that we may truly serve ourselves.

---

* Address before the graduating class, St. Louis University School of Medicine, June 1, 1914.

I have led up to this thought with three objects in view: First, to make clear to you that knowingly or unknowingly each of you is bound to adjust his life between the ideals of egoism and altruism. Should it not be knowingly? Should not each move in your career be determined after consideration from both points of view? For one I trust that the latter may be your method of planning your lives—thoughtfully, courageously, with due regard for yourselves and others.

Secondly, I wish you to see that more and more through the ages the altruistic note has become dominant in human affairs. First it was the family for which man limited his individual freedom. Next it was the neighborhood. Next, the tribe. Next, the nation. And with each recognition of altruistic obligation has come further surrender of the individual and further advance of civilization. To-day it may be prophesied safely that no individual right, whether of property or person, will be allowed permanently to stand which conflicts with the prosperity, happiness or health of the organized whole. You will note that I have used the word health here for the first time. The right of society to health is one of the latest rights to be recognized. The right and duty of society to secure and protect health are bound more and more to come to the front as prime motives in limiting the individual. This is a fact of growing significance. It is bound to affect your lives. I shall return to this topic later in this address. For the present I wish to advance my third reason for discussing individualism and altruism. It concerns your chosen profession. Medicine began and has continued until recently quite strictly as an individualistic calling. The nature of the profession led inevitably to this history. Men are sick as individuals. Treating their ailments began as a personal service. As society advanced the intimate relation of patient and physician came more and more to be emphasized. Reasons of business expediency, of personal modesty and of family intimacy made the relation confidential. The individualistic desire to get well is an instinct ever clamorous and insistent, whereas the social value of health is an intellectual concept only slowly gaining acceptance and still more slowly becoming a moving force. We willingly pay to be relieved of individual pain and immediate bodily embarrassments. We have not yet achieved such breadth of vision as to pay to be protected from that which threatens the social body, but may not come to us individually.

Thus medicine grew up and is to-day very largely a personal service. Each of you in a certain sense is going into business. You have something to sell. You will look for a market. You will sell to him who desires to buy. You will take your pay. You will sell to some who cannot pay; to some who will not pay. And just as in every other business, you will make those who do pay pay also in the long run for those who fail to pay. This is the rule of trade. It must be followed if you would succeed financially. It is the inevitable result of the individualistic position of medicine at the present day.

With the knowledge, however, of the nature and cause of disease acquired in the last half century, a change has begun whose effects are already plainly perceptible and whose eventual far-reaching results over your profession no one at present can foresee. We know now that disease is never wholly an individual matter. Some diseases are *predominantly* social. Consequently your relation as physician, to persons afflicted with these diseases must involve a relation to the whole social body. You cease to be merely a seller of merchandise. Your dealing is no longer exclusively with the individual. You become the servant of the whole people. Society already places explicit duties on you; and by implication requires many more. As time goes on it will demand still others. Medicine is losing its individualism. This you must recognize and you must adjust yourselves to the new condition. More than that, you must lead, if you are men worthy of these diplomas, you must lead society in the great movement to eliminate disease. You must become less and less the sellers of healing and more and more the captains of health. This means in the end a broader responsibility and a more dignified station. But meanwhile, it means readjustment and possible hardship. How are you of the next generation of doctors going to face this great social movement? Are you going to sit back on the cushions of ancient privilege? Are you going to rest content on ideals of personal service? Or will you rise to the concept of higher duty? Surely these things are worthy your best thought as you enter and carry forward the work of your profession.

It is therefore not in any ordinary spirit of interest but rather with high inspiration that you are asked to consider more specifically, for these last few minutes, some of the movements and signs of the times.

THE PUBLIC HEALTH CAMPAIGN

First there is the wonderful and far-reaching activity known as public health or preventive medicine. This movement finds its scientific foundation in Pasteur's demonstration of the cause of disease and the nature of infection. It finds its mathematical verification in vital statistics. It finds its financial justification in the value of the human animal. But it finds its moral justification in the altruistic ideal of race welfare and community happiness.

It is hard to discuss this question without resort to statistics. We might show that the average length of human life in Europe has increased from eighteen or twenty years to over forty years. We might quote the death-rate in New York City as 36 per thousand in 1866 and 14 per thousand in 1913. We might estimate what this means to the wealth of the world, when considered "in conjunction with the simple proposition that *wealth is always and only the result of human labor.*"

On the other hand, we might point to the enormous work yet to be done. We might dwell on our national crime of 1,100 preventable deaths a day—fifty lives, perhaps a hundred, in this land of ours, snuffed needlessly out while we sit here during these exercises.

However, figures are dry; statistics do not comport well with commencement joys. I shall content myself with authoritative quotations which ought to stimulate the thought and arouse the activity of every person present.

Says Disraeli:

> The public health is the foundation on which reposes the happiness of the people and the power of the country. The care of the public health is the first duty of a statesman.

Says Pasteur:

> It is within the power of man to make all the infectious diseases disappear from the world.

The significance of these statements for every man and every woman everywhere is easily appreciated. If there is such a thing as social consciousness, then each of us contributes to that consciousness. If there is such a thing as group activity, then each of us must either engage in that activity or act as a drag on social progress. If there is such a thing as group responsibility, then each one of us is responsible. Who shall doubt that there is such consciousness, such activity, such responsibility? Only he who denies absolutely the altruistic ideal. It behooves us, therefore, each and every one to study, endorse, support and actively engage in the public health campaign. If we do less we are false to our duty as men. This applies to all men. It applies particularly to physicians.

But wherein lies the special plea to the medical profession and to this graduating class? Exactly in this: The doctors must be the explorers and pioneers of this great movement for race betterment. This mission they are attempting in every way to accomplish. They *ought*, further, to be the active leaders of public sentiment, the molders of political action and the most scrupulous supporters of every legal regulation. Can the doctors qualify for the latter high offices? I regret to confess my belief that they cannot so qualify.

It is true that physicians as a whole give assent to the principles of preventive medicine. They endorse the health movement, although they know it means diminution of their business. Moreover, practically without exception, they practice those methods of routine in their professional work which are calculated in a measure to limit the spread of disease. Through their associations they carry on an active and valuable campaign of education, and assist in the indispensable political propaganda.

It is as individuals that they fail. And they fail because they still take the narrow individualistic view of their work. They get the patient so close to their eyes that they cannot see the public. They consider their trade and fail to recognize their profession. How many of them, for example, find it convenient to fail to report cases of infectious disease? How many connive at violation of quarantine? How many give weak support to public officials in health matters? I may be wrong in the impression that the number guilty of all these offenses is large. But I am not wrong in the observation that far too few physicians are accurately informed on matters of public health. Far too few are leaders of public sentiment. Far too few even make serious effort to educate their own patients in their public duties. Many valuable measures fail through the indifference of the profession. Many reforms are delayed for years because the doctors are afraid to be reformers. Moreover, one need not search far to discover evidences of active opposition. In England the medical association opposed to the last moment the great insurance act.

You may say that one should not expect the doctors to be different from other people when they see their business involved. But these are educated men and should be alive to the spirit of the times. Many of them are behaving at present much as did the spinners and weavers when power machinery was introduced. Surely the most highly trained profession should rise above the motives of ignorant workmen.

Says Macilwaine:

> The overwhelming majority of the profession do not concern themselves with prevention.

Says Ditman:

> Disease, crime, pauperism, insanity and preventable accidents are the foulest blots on the modern civilized state, and the responsibility for the amelioration of these curses must be faced on the last analysis by the medical profession.

You may point to the important accomplishments in sanitation and public hygiene, and claim the credit for the medical profession. I grant the importance of the achievements and acknowledge in large measure the justice of the claim. These accomplishments, however, involved for the most part, the control of matter and natural forces—what has aptly been termed the "non-human environment." They were largely engineering problems such as water-works, filtration plants, sewers and garbage incinerators. Or they involved control of lower forms of life such as mosquitoes, ticks and rats. The things that are to be done are vastly more difficult because they involve the human animal. Every step from now on must begin with a limitation of individual freedom and individual rights to property. Inherent and heedless egoism is the great barrier to progress in preventive medicine. Not bricks and cement, but human psychology is the material henceforth to be worked on in public health. Only by the painfully slow process of education can the altruistic motive gain ascendancy, and only as such ascendancy is gained will control of the preventable diseases be realized.

In this tremendous but not superhuman task of education the doctors must take the lead. And in proportion as they realize the task and work on it with all their strength, privately and collectively, with their patients as individuals and with the public at large, only thus will they realize the fulness of the term "doctor," which means primarily *one who teaches*. Remember this all ye physicians. And you who to-night receive your diplomas, whenever you look at those documents framed on your office walls, translate in your hearts the words *Medicinae Doctor* into "Teacher of Medicine," and exalt your profession thereby.

One might easily fill a longer time with the enticing theme of public health, but I desire only to hint at things which should stand in large outline as you begin your careers and leave to you to fill in the details. I pass to the related topic of social service.

SOCIAL SERVICE

This too is a pregnant subject. There is a little book by Richard Cabot which every one of you should read. The title is "Social Service and the Art of Healing." You should read that book, I repeat; and if for two years you have passed from clinic to clinic and have not learned how the problem of disease links up inevitably with the problem of poverty and the problem of crime and the problem of ignorance and the problem of heredity and all the other great sociologic problems—then, I say, you are already suffering from that medical blindness which Cabot so clearly portrays. He shows how even in the narrow duty of doing your best for the patient you must look at the background of social conditions. You must look back of the *patient* and see the *man*.

Somewhere else I have read how the physician's classification of diseases according to tissues or poisons or micro-organisms tends to blind the vision to the true causes lying back of all in social and industrial conditions. I need not give examples to prove to you that this statement is true, but I do wish to emphasize its importance. "It is quite clear," says one writer, "that, practically, the elucidation of antecedent conditions may often be vastly more important than the immediate and individual problem of diagnosis." Think of the absurdity of that procedure to which many have called attention, but which exists everywhere in public hospitals and private practice alike—I mean that procedure by which a patient, at large expense of money and effort, is brought to a condition of health and is then turned back into the environment which was the real cause of his disease. This procedure, narrow and unwise in the case of an adult who may be able in some cases to modify his environment, change his employment or his habits of living, becomes actually a social crime when the patient is a little child.

If you are to succeed in medicine even in the narrow individualistic measure which has constituted success in the past, you must cure people so that they will stay cured. Therefore, you must not fail to look at the social background. You must learn to deal with the whole man physically, environmentally, psychologically. You must become proficient in the "study of character under adversity and of the influences that mold it for good or ill;" and that, if we accept Cabot's definition, is to be a social worker. Moreover, you whose *chief* business, admittedly, is the diagnosis and treatment of the ills of the body, will join hands with that new expert who diagnoses and treats the ills of environment and of state. You will call on him for assistance as on any specialist. You will return service for service. You will pull your oar joyfully and manfully in that "team-work of doctor, educator and social worker," whose object is "the care of people in trouble."

This address might have been called "Cooperation in Medicine," because its central idea is to show that medicine like every other human activity tends toward collectivism, toward cooperation. The matters of public health and social service already discussed are two important cooperative enterprises in which I believe that every doctor should take active part. I come now to cooperation in a narrower sense, namely, union of effort to care rightly for the individual patient. This union of effort takes two distinct forms. First, the joining of individuals into a group to care for the ills of the members of the group. Second, the joining of doctors in order the better to care for their patients. Under the first head are included various charities, the fraternal lodges, various forms of insurance societies and companies, industrial concerns and the state or municipality itself, in so far as this largest group makes medical provision for its members. Here we have a complicated and difficult matter; a matter of ever-growing importance, which may change absolutely the social status of medical practice; yet a matter on which medical men are prone to take wrong or at least narrow views. The phrases "contract practice," "company doctor," "sickness insurance" are terms of opprobrium to most of the medical profession; yet the facts and the logic of these facts are simple. You should face them, think them out, adjust your lives to them.

As to the facts: there is first the "submerged tenth" of the population, whose income is always too small for the imperative necessities of proper food, clothing and shelter. When they are sick, they are "down and out." They cannot possibly care for themselves, to say nothing of paying a physician. They must be dependent on some form of assistance or die. Humanity revolts at the latter alternative. Moreover, we are learning that the menace of disease spreads ever from the lowest to the highest orders of society. Organized charity and the state itself, therefore, give freely and largely for this class of unfortunates. Public and charity hospitals and dispensaries are maintained on ever-enlarging plans of material equipment and professional efficiency. The doctors give freely of medical service and administrative knowledge. The very poor in many cities get as good medical service as the rich. On the whole, the lack of inclination and power on the part of society to deal effectively with the underlying and responsible social conditions is the hard and almost hopeless problem as regards the submerged poverty-stricken portion of the population.

But now we come to a second great group of people, composed chiefly of wage earners whose income, so long as they remain in health and have work, is sufficient for the needs of themselves and of those dependent on them. Here are classed the great body of self-respecting laborers and artisans. They are in no sense dependent; on the other hand, they are the backbone of industrialism. It is before the member of this group that ever hangs the imminent possibility that when he gets sick, he first of all will lose his job and secondly will be expected to support his family and pay the doctor. Even in good times and good health many fail to keep more than head and shoulders above water. Illness or non-employment means inevitable submersion. It means drowning unless some form of life preserver is thrown out. Now what is more natural than that this life-preserver should be provided through the cooperative effort of a group, or through the cooperative effort of industry or through the cooperative effort of society as a whole? The first means the lodge or union. The second means the company physician or industrial medical organization. The third means governmental insurance or state medicine.

You have to regard the situation in one of two ways. If your point of view is narrowly individualistic, you may say that the laboring man must maintain himself and bear alone the exigencies of industrial depression, the chance of disease or accident and the inevitable incidence of age. You say, perhaps, that the public is not concerned except to care for the absolutely helpless and the hopelessly indigent. If this is your point of view—and it is a very common one—then the least that you can do is to face the responsibility which your scheme of society involves. You must recognize that your plan must force over the line into the submerged portion of the population many an individual and many a family on whom come, through no fault, perhaps, of themselves, the curse of non-employment, accident or disease. And you must face the fact and the responsibility for the fact that every man so forced over the line into dependence loses something of incentive to labor, something of manhood, something of self-respect. In losing these, his regard for society and law must diminish and his inclination toward parasitic existence must increase. When you consider that sixty-two out of a hundred persons seeking aid from a destitution agency were driven there by illness, you begin to comprehend how serious is your responsibility as medical men if you insist on the individualistic scheme of social organization.

The other point of view is altruistic or, if you prefer, collectivistic. It says that the social order (widely or narrowly considered), is responsible for those accidents which we call sickness and lack of employment. It looks on disease and old age exactly as we have all come to look on fire and burglary and the hazards of the sea. It says that society should carry the burden of all these exigencies. The individual should not be released, but he should bear only his share of the load. All this broadly considered is insurance. It may be government insurance, paid for by taxation, such as the protection afforded by the army, the police, the fire department. It may be corporation insurance as our ordinary types of life, fire and tornado protection. It may be cooperative insurance as in fraternal orders and friendly societies. Whatever its form, the philosophy of insurance is that each participant contributes in proportion to his share of the risk. Not all receive back what they put in. Of a thousand houses insured we expect only a few to burn. But the man whose home does burn receives a much larger sum than he paid in. He receives it gladly and with no stigma of dependence, as would be the case if his friends took up a collection to pay for his house. Surely this form of protection should apply as usefully and properly in meeting the exigencies of accident or disease as those of fire or theft.

Now the medical profession does not object to insurance. Indeed, it approves very heartily when the life insurance comes in at just the right time to liquidate the deceased patient's bill. It highly approves of insurance against malpractice and against automobile injuries. But when insurance attempts to provide medical attendance for a group of poor workingmen, the medical profession is inclined to exclaim in holy horror against the invasion of its ancient prerogatives. It holds up its time-stained right of fee as a banner more esteemed (for the moment) than the noble right of service. It says: "These men pay only fifty cents a month. Do you think we will give any one medical service for fifty cents?" It loses sight of the analogy of the many houses that never burn, but whose owners through insurance pay for the loss of the one that does burn. It loses sight of its own manifold losses from persons who cannot or do not pay. It loses sight of the advantage, even to a doctor, of a fixed income. It fails lamentably to look at the greater good, which is the public good.

With this attitude of many of the medical profession I have little patience nor will the public long have patience. I will grant that many of the schemes proposed have been chimerical; some of them, fraudulent. Most of their promoters have aimed at cheap medical service, not efficient medical service. I will grant and I will work for the proposition that the medical profession should be properly compensated and that matters should be so arranged that the patient shall have free choice of doctors. I will grant the advantage of such elements of competition in medical practice as tend to develop the best service. But granting all these things and balancing these and the other valid objections against invalidity insurance over against the good which would come from a thorough-going system, I find the scale coming down heavily on the side of the latter; and I am sure that the same conclusion will be reached by most, if not all, physicians who open-mindedly study the working of the insurance laws in Germany, Denmark and Great Britain. The objections of the British Association have not been warranted, for the brief experience with the new law shows that the compensation of the profession has been appreciably increased.

This question has not assumed large proportions in this country, but I am certain that it will do so in the not distant future. It is manifestly impossible to discuss it adequately on this occasion. It will demand the highest wisdom to secure a system adapted to our peculiar conditions. Like all the other topics which I have touched on, I bring this before you for thoughtful study as you go about the practice of your profession.

The second form of cooperation for the care of the individual patient which I mentioned was that of the doctors themselves. Of course the consultation is a long-established attempt at such cooperation; but that its usefulness is very limited, as ordinarily carried on, there can be no doubt. Whatever good there may be in consultation (except in hospitals), has accrued almost exclusively to the wealthy patient. Surely medicine will never be rightly adjusted in the social order until every man, woman and child is entitled to receive and actually does receive the best oversight and treatment that science is able to afford. This is not the case at the present time.

There are various reasons for this condition. One of the most potent is the ever-widening specialism in medicine. Of the inevitable necessity of this movement there can be doubt. No one can hope to compass the tremendous volume of medical fact or become proficient in all the valuable diagnostic, therapeutic and operative procedures. Specialism in any line of endeavor, whether medical or otherwise, tends to narrow the field of activity and of vision. Concentration increases intensity at the expense of distribution. It acts in human activity exactly as in the electrical transformer: if you increase the voltage, you decrease the amperage. The practical point is that for certain patients the work of several experts is necessary, if the best results are to be obtained. How well has medical practice succeeded in adjusting itself to secure these benefits for the individual case? In my judgment it has not succeeded. It is true that in the best charity hospitals the very poor individual receives the services of all the necessary specialists and all the modern appliances. For the small group who can pay large fees, there is possibility of getting what is needed by reference from specialist to specialist and the paying of separate fees for each element of service. The doctors may think that this procedure works well. In my opinion it does not work well even for the doctors, taking their interests broadly; and from the patient's point of view it is subject to the criticism that they interpret the multiplicity of fees as repeated payments for a single service. They look on specialism as a new device for padding their pocket-books. But the fatal fallacy of the present arrangement is its inapplicability to the great class of independent poor, who cannot by any possibility meet the repeated demands for even moderate fees. They simply go without the service; and of course, the doctors cannot render it.

Now it seems to me that a hopeful movement toward the solution of this difficult problem is found in those combinations of experts, however arranged, by which the sick man becomes the patient of the group, which renders the service needed for a single charge. The system and efficiency secured by these organizations are almost uniformly admitted. You may criticize the scheme as destroying the individuality of the doctor's work. I cannot see that it does; but even if this were true, I believe that something better, namely, an improved service, is substituted. You may make the charge that these institutions tend to commercialize medicine. Again I cannot see your ground for argument. I believe, on the contrary, that their organized systems of arranging compensation are more just than the haphazard methods of the ordinary practitioner. If the system of fee, that is, of charge proportionate to the financial ability of the patient, is in any way or anywhere defensible, then these organizations certainly administer the system with as full regard to the means of the individual patient as do medical men who work as separate units.

But let us throw to one side these more or less specious and minor criticisms and ask whether the examples of medical cooperation meet a social need? Do they bring to the individual patient what he ought to be entitled to, namely, all the expert service that his case demands? Do they accomplish this end better for the average patient, all things considered, than the same experts would do working separately? If so, common sense must justify this departure from time-honored (which often means worm-eaten), custom. However, as with all other problems which I have discussed, I do not ask you to accept my views in regard to this question. I ask you first to recognize the problem. But I ask you to do more than recognize. I ask you to study it in the light of the broadest spirit and fullest knowledge attainable.

There are various further topics that I had hoped to bring to your attention. There is the suggestion of regular medical examinations for persons in health, a problem which some of the life insurance companies are experimenting with.

The army of the pick and shovel, of the saw and trowel, far overshadows in its importance to the nation the army of the rifle and sword. Yet the latter army takes every precaution through its medical organization to keep the individual soldiers at the highest point of efficiency, while the great army of industry moves forward with the savage individualism of the hoards of Attila. Medical science so far has been content to follow in the rear and pick up the wounded. Should it not go in advance as did the medical officers of the army of Japan? We all know that the true function of medicine should be to keep people well. They should be regularly watched for evidence of disease and given timely advice and treatment. We know how present economic conditions, medical ideals and popular psychology tend actually away from rather than toward the proper relation of medical science to the social body. We read Samuel Hopkins Adams' interesting story of the "Health Master" and are filled with regret that only in fiction is such a character to be found. It is a hopeful sign, however, that people are beginning to think of these things.

This topic I pass with a word. Others as important I omit altogether. I have said enough to fulfil my intent, which was to show that there are many things concerning which you must "learn what is true in order to do what is right." You are going forth to work. Twenty, thirty, perhaps forty years of active service stretch out in front. At the end, what? Will you be like Sylvius?—a great physician, but one whose epitaph is the epitome of self-centered existence.

> Here lies Sylvius who never did anything unless he was paid for it. If he could do it, he would charge you for reading these lines.

No, I cannot think of you as like Sylvius. You are forward-looking men, alive with the spirit of the times, kindled with altruistic enthusiasm. You know that there is something to your profession and something possible to your lives, besides appendicitis and typhoid and pneumonia; something besides office hours and calls and long rides over country roads; something besides bills receivable and bills payable; something besides the individual patient with his idiosyncrasies and his pains. There is world interest; there is world importance. There is room for the scientist's logic, the soldier's heroism, the stateman's wisdom, the reformer's fervor, the poet's imagination. There is room for much living and much thinking. The world with all the centuries wrinkling its forehead; humanity with its accumulated accomplishments; art with its visions of ecstasy and beauty; science with its hard-worn hoards of learning; all are as new to you as the flowers of Eden were to Father Adam. Go forth and strive. There is

> Something hidden. Go and find it. Go and look behind the Ranges,
> Something lost behind the Ranges. Lost and waiting for you. Go.

THE NEGLECT TO PROVIDE FOR THE INFANT IN THE ANTITUBERCULOSIS PROGRAM

ALFRED F. HESS, M.D.
NEW YORK

In the warfare against tuberculosis we should consider ourselves particularly fortunate in possessing full knowledge of the cause of the disease which we have to combat and a fairly complete knowledge of its mode of transmission. Probably the greatest advance which has been accomplished in this field during the past few years has been our clearer conception in regard to the time of life when infection takes place—the realization that tuberculosis is contracted to a large extent in early childhood. This brief report is written from this point of view, with the purpose of raising the question whether we are making use of this new knowledge—whether our methods of prophylaxis have advanced or have been reconstructed to harmonize with it. We know not only that infection occurs during early childhood, but that it occurs frequently in infancy, and that the younger the child the graver the prognosis of the disease; infants infected when under 1 year of age rarely recover, and those between the ages of 1 and 2 years have a very poor outlook for life. With these statements as a preface—facts which now constitute every-day medical knowledge—we may well inquire what is being done in the antituberculosis campaign to prevent infection at a time of life when it not only occurs frequently, but runs so grave a course? What measures have been added to the sanatorium treatment, to the provisions for home care, or what new organized effort has been launched, which promises to safeguard our infants against tuberculous infection?

This question recently has presented itself for solution under the following circumstances. At the Tuberculosis Preventorium for Children at Farmingdale, N. J., two hundred children are cared for, who give a positive tuberculin reaction, but show no clinical signs of tuberculosis. They range in age from 4 to 14 years, and are selected by the tuberculosis dispensaries of New York City from households in which some member of the family is tuberculous, frequently suffering from open tuberculosis. These two hundred children, at the present time, happen to represent 120 families, as, in many instances there are several from one and the same family. A chance occurrence, the visit to the preventorium of a sickly tuberculous mother carrying her infant in her arms, suggested that it would be of interest to inquire how many more infants under the age of 2 years there were in the 120 homes of the children at present in the institution. It was a simple matter to secure this information. Not only did we have the data on the admission-cards, but we could question the children themselves. By this means we were able to obtain far more accurate information than if we had undertaken a larger investigation embracing children no longer in the institution.

The result of our inquiry showed that *there were forty-two infants under 2 years of age in these 120 homes* A most startling situation! The accompanying table gives a summarized picture of the individual families. From this table it will be seen that in very many cases there is more than one member in the home suffering from tuberculosis; that frequently the tuberculous disease is in the second stage; that in many families there are two infants exposed to infection; that even when the tuberculous individual has left the home for a sanatorium, this removal has occurred so recently that the infants have been exposed for many months; that the number of children in these families is unusually large, averaging somewhat over five to a family.

It is apparent that this investigation portrays a very serious condition of affairs, and that unless some protective measure is taken, these infants are doomed to tuberculosis, leading to illness, to the dissemination of infection, and to death. What shall be done in the matter? How shall we protect them and the community? The first relief measure which suggests itself, probably, is to send the tuberculous mother or father to a sanatorium. We find in practice, however, that it is feasible in only a few cases to safeguard the home by sending away the tuberculous member of the family. The mother cannot be spared from the household, for the very reason that she has the infant to care for, as well as because there are usually other children. (It will be noted that the mother constitutes the tuberculous member in over one-half of our cases). The father, although tuberculous, is still in many instances an important source of income for the family; he cannot desert them. There is therefore the necessity, in a large proportion of the cases, of focusing our efforts in another direction, of striving to send the infant out of harm's way. A few who are orphans or half orphans can be committed to orphan asylums; a few others, provided the breadwinner is ill, may be looked after by some existing child-caring institution. If, however, the family is not destitute, if there is a source of income sufficient to keep it afloat, it will be difficult to place the child in an institution. The babies' hospitals can offer no refuge; they must refuse to fill their beds with infants who are not sick. At a loss how to solve the problem, and feeling that there might be some unexplored avenue of escape, I appealed to the Commissioner of Public Charities, Mr. John Kingsbury, for advice. He answered in the main as follows: "In so far as I have been able to gather, and I have caused diligent inquiry to be made, at the present time we have no agency or institution in this city equipped to care for the particular class of children you describe."

In order to have the question concretely in view, it may be well to cite a case in point. Let us examine

DATA OF THE 42 INFANTS IN THE HOMES OF CHILDREN NOW AT THE PREVENTORIUM

Case No.	Initials of Child	Age in Years	No. Children in Family	Tuberculous Members	Stage of their Disease	Location, Etc.
1	G. B.	1	8	Father	2	In sanatorium 2 months
2	G. B.	2	..	....	..	....
3	W. B.	1	8	Brother-in-law	2	Home
4	I. C.	6/12	7	Mother	2	Home
				Father	2	Home
				Sister	2	Sanatorium

				Sister	1	Home
28	S. R.	2	4	Father	1	Home
29	S. R.	8/12	..	Mother	1	Home. Four children died
30	F. R.	1 1/12	3	Mother	2	Home
31	F. R.	3/12	..	Father	1	Home
32	P. S.	1 5/12	6	....	..	An arrested case
33	E. S.	2	5	Father	3	In sanatorium?
34	R. S.	2	4	Mother	1	Home
35	R. S.	1	..	....	..	....
36	M. S.	1½	4	Father	1	Home
				Mother	1	Home. Do not care to be burdened with children
37	J. S.	2	3	Father	..	Died of tuberculosis at home year ago
38	H. S.	1	3	Mother	2	Home. Cannot leave on acct. of infant
39	M. S.	9/12	5	Mother	1	Home
40	F. W.	2/12	4	Mother	2	Home
41	M. S.	9/12	5	Mother	1	Home
42	J. S.	1½	3	Father	2	Home

more fully the instance which we referred to above, and which led to this investigation:

> Family H. S. There are two children at the preventorium for the past three months who are doing very well. The father appears to be in moderately good health and earns $10 a week. The mother looks weak and sick and has tuberculosis in the second stage. On being asked why she did not enter a sanatorium, she replied that she could not leave home on account of her 15-months-old baby, which she was carrying in her arms. Further questioning elicited the fact that she had been well until this last child was born, and had weighed about 135 pounds; that since this time she had failed and now weighed about 100 pounds. The recency of active tuberculosis in her case probably explains how it came about that the two older children did not succumb to infection in infancy. This infant evidently could not be sent to a hospital or to an orphan asylum; at best it could be referred to some other institution for a short period. In order to provide for this emergency, we at once admitted the infant to the preventorium. This provision enabled the mother to leave her home and to enter Sea View Hospital a few days later.

It would seem that we have here encountered a weak link, not only in the antituberculosis movement, but in the infant welfare work as well — for these two fields of effort overlap or rather dovetail at this point. Unless infection of young children is adequately guarded against, what basis is there for any hope of eradicating tuberculosis in succeeding generations? Many of these infants will die; others will live to constitute a large proportion of the patients who are destined to waste away in their homes or to fill the preventoriums and the sanatoriums in the generation about to come. How then are we to provide for these infants? The suggestion to protect them in institutions is rejected as impracticable; it is argued that mothers will not part with their healthy infants, and that we cannot exercise coercion. Although this contention has from time to time been made, I know of no experience to substantiate it. In view of the seriousness of the situation, of the thousands of infants who must be exposed to infection in the city of New York, it would seem worth while to ascertain, by means of a vigorous experiment, whether tuberculous parents will give their children up to institutional care. I believe there is a considerable number who will be sufficiently wise to make this sacrifice when the danger lurking in a tuberculous home is adequately explained. The weak and sickly mother suffering from tuberculosis will be particularly inclined to temporarily renounce her infant, and it is in her case that a separation is most urgently demanded. *Tuberculosis preventoriums for infants should be established.*

To make a beginning in this direction it may be advisable to assign wards for this purpose in existing institutions (infant asylums, preventoriums or sanatoriums) rather than to establish new institutions. In this way it would be feasible to have, in many instances, infant and parent in the same institution. These infants need not be sent to the country, to be treated by means of a rigorous fresh air régime; they may be adequately cared for in or near the city, where their parents have the opportunity of visiting them from time to time. Preference might be given at the outset to urgent cases, to infants surrounded by open tuberculosis, to cases in which a tuberculous mother is constrained to remain at home in order to care for her infant, or in which there are two or more members of the family suffering from tuberculosis. The minimum length of stay may be fixed provisionally at one or two years.[1] The details of organization, however, cannot be formulated in advance. The object of this paper is rather to urge those engaged in tuberculosis work, as well as those active in the field of infant welfare, to make some provision for a large number of infants who are now abandoned to their fates, destined to die or to swell the ranks of the tuberculous poor in the coming generations.

16 West Eighty-Sixth Street.

THE HEART IN THE ACUTE INFECTIONS *

ROBERT N. WILLSON, M.D.
PHILADELPHIA

More and more generally is the fact being realized that the heart suffers in greater or less degree in every acute systemic infection. We may safely go further and state that there probably occurs no instance of perfect cardiac recovery from an acute micro-organismal invasion. This must not be taken to mean that there are no clinical recoveries from the cardiac complications of the acute infections. It does indicate, however, that a scar results from every attack on the cardiac musculature and on the endocardium and pericardium, and that cardiac scars spell weakness, not strength.

Not infrequently, especially in the acute diphtheritic involvements, the pulse will become mean and thready, cyanosis is extreme, sweating profuse, nausea and vomiting appear, the blood-pressure (systolic as well as diastolic) falls, and the patient may die with all the phenomena of shock. Such a patient dies primarily from structural damage to the cardiac mechanism, due to the toxin circulating in the blood. McCallum[1] has shown that there are other factors at work, also, since the insufficient heart may be revived even after the death of the patient, and resume its function for a time. But the microscope reveals lesions amply sufficient to account for every failure in the performance of duty.

It is well to remind ourselves that in certain instances of clinical recovery the heart not only fails to regain its full integrity, but dates its first clinical insufficiency from the acute systemic attack. The picture may be classified as the debility of convalescence, or as a postfebrile anemic state, or what not. The important point is that too seldom is the condition recognized as a real loss and lack of ability to maintain cardiac muscular tone.

Probably all of the acute infections are micro-organismal, if not bacterial in origin. Even syphilis may now be classed within such a category. Rheumatism also seems ready to fall in line, perhaps as a genuine streptococcemia, possibly as a symptom-complex variably dependent on now one, now another causal germ. The pneumonias acknowledge no one bacterium as their invariable underlying factor. Tuberculosis, like influenza, almost always appears as a mixed infection. Measles, small-pox and scarlatina appear to be drifting, more by dint of fashionable tendency than by reason of any definite demonstration, into the streptococcic fold. Only diphtheria, typhoid fever and syphilis—already mentioned—furnish clinical cardiac conditions distinctive, even in a measure, of a definitely recognized organism and demonstrably characteristic lesions.

---

[1] In many instances it will be found that the *problem* of infection in the home has solved itself in the course of a shorter period, the tuberculous member having died or entered a sanatorium, or the disease having become arrested.

* Read at the annual meeting of the Pennsylvania State Medical Society, Pittsburgh, September, 1914.

[1] MacCallum, W. G.: Am. Jour. Med. Sc., 1914, cxlvii, 37.

Roughly speaking, we may generalize or group the harmful effects of the active agents in all of the acute diseases into those of (1) acute true myocarditis, (2) myocardial atony due to degenerative change, (3) toxic paralysis or paresis of the cardiac muscle and nerve fibers, (4) endocarditis (valvular and mural), (5) simple and mediastinopericarditis, and (6) muscular and valvular insufficiencies with dilatation of the cardiac chambers.

I make no reference here to the sclerotic changes that may or may not have had their beginnings in an infectious thrombo-arteritis of the vasa vasorum during the acute disease. Nor may we stop to consider the many post-convalescence developments that may easily be traced back to the acute infection of weeks or months previous. I shall not even dwell on the central involvement of the vasomotor system, the importance of which has, until the recent reaction, been exaggerated beyond all warrant. I have shown in another place[2] that in the pneumonias, at least, the diastolic blood-pressure (the best index of vasomotor tone) maintains a fairly normal level. Schwarzmann[3] has recently come to similar conclusions with respect to eighty cases of the various acute infectious diseases.

ACUTE TRUE MYOCARDITIS

True inflammatory involvement of the myocardium varies in type and extent in the acute infectious diseases from the simplest edematous infiltration or localized round-cell infiltration to the characteristic nodules of Aschoff, found in the hearts of subjects suffering from genuine rheumatism and chorea. There may be evidences in the myocardium of attacks antedating that which proves fatal, such as areas of old fibrous tissue, side by side with new inflammatory processes, or such as the scars and fibrous patches representing healed Aschoff's bodies, accompanying newly formed and typical giant-cell colonies. If the heart has previously been free from disease, the musculature of the left ventricle is most likely to suffer. It may, however, be the right ventricle wall, or the muscular ring supporting the aortic and mitral valves, or the atrioventricular bundle, or that less commonly known tract of transmitting fibers described by Kent as existing in the right lateral cardiac wall. Here, there, or everywhere the lightning may strike and leave its fingermark.

The vital point to which I would here call attention is that whether the infection be a pneumonia, a gonococcemia, a rheumatism (so-called), an invasion by the *Streptococcus mitis* (*viridans*), or by the homely staphylococcus, if it becomes general and severe, the cardiac musculature invariably suffers and the microscope will reveal lesions competent to explain many features of the clinical picture. Once this fact is appreciated as a general principle, we shall cease emphasizing the all-importance of a loss of vasomotor tone, especially since, as in most pneumonias, the vasomotor tone is not low. Moreover, we shall be more likely from the beginning to watch intelligently and closely for the early signs of cardiac irritability, and later for indications of cardiac distress. A weak, irregular pulse, air hunger, pain that cannot be definitely attributed to pericarditis, precordial oppression, will all have a new significance when we realize that the main lesion even in rheumatism is of the myocardium, not of the valves, and is just as likely to be permanent as if it were valvular.

Acute syphilis is as likely to cripple the myocardium as the valvular structures, and to leave unmistakable evidence of the nature of the process in the presence of the spirochete. The changes may be interstitial or parenchymatous or both, and may vary in grade from an edema to fatty degeneration. Except in the late fibroid lesions the spirochete will usually be found. Very rarely does the heart of syphilis escape being the heart of myocardial disease.

In a brief paper it is manifestly impossible to cover thoroughly the ground suggested by the myocarditis of acute infectious disease. One can, however, and should have instantly brought to mind, when diphtheria presents itself, the fatty degeneration of the fibers and the paralysis of the cardiac nervous mechanism, even more vividly than the localization of the membrane in the pharynx, larynx and nose. In typhoid fever the hyalin or waxy degeneration (Zenker) of the fibers is not to be forgotten. In the pneumonias, I have elsewhere shown that we may confidently expect any or every grade of degenerative change. In influenza many patients die in their convalescence as the result of fatty myocardial change. In true rheumatism we find not only any or all of the changes mentioned above, but in addition the suggestive, if not pathognomonic nodules of Aschoff in and around the adventitia of the small subendocardial vessels, in the interstitial substance between the fibers, even in the valve structures themselves.

I have seen two instances of suppurative involvement of the cardiac muscle, both in cases of pyemia, the one an example of extensive suppurative myocarditis, and the other of multiple abscesses of the heart wall. Cases of this sort are always fatal, and are diagnosed by generalization only, or on the necropsy table.

Whether full cardiac recovery follows even the milder grades of infectious inflammation, and whether a heart so involved is ever again quite ready to perform full service, I think we may, on the basis of the foregoing, very well doubt. For ordinary purposes it may answer every need. When the stress comes, just as during the primary acute illness, it may be taxed just a little beyond its capability, even though well within normal limits, and fail the patient at a time in which he needs every reserve force and energy. In the form of atrophied or degenerated fibers or localized areas of fibrosis the heart may preserve its record of the storm. Many a physician has experienced a severe clinical lesson in the loss of a patient owing to sudden cardiac failure when convalescence has seemed almost or quite complete, even when the primary disease has been not oversevere. Weill and Mouriquand[4] have reported a series of such instances in convalescents from scarlatina. In one case, a girl of 15 years died suddenly at stool. Another child, an infant of 18 months, died suddenly when it seemed past all need for worry. The microscope revealed an acute myocardial inflammation as the cause of the fatality. Far more frequently does diphtheria cause such an end.

---

It would seem, then, that the heart muscle is of primary interest in the acute infectious diseases, and deserving of more than ordinary concern.

MYOCARDIAL ATONY DUE TO DEGENERATIVE CHANGE

The various forms of degeneration noted in the myocardium of infectious disease have already been briefly mentioned. They all lead to some measure of disability and incompetence, mainly as a consequence of a loss of muscular tone. This quality or function of being fit, or, to use athletic parlance, "on one's toes," is as essential to cardiac equilibrium as it is to the performance of a person's daily work. If he possesses that indescribable something which insures his mental and physical grasp of things, the vital tension that furnishes both energy and endurance, he enjoys the tasks of the day. He is a giant and they are the duties of a Lilliputian. Exactly so with the cardiac muscle. If tone is lacking, every emergency is a new burden. We must not forget, moreover, that the arterial system is simply a continuation of the structural architecture of the heart. That which lowers cardiac muscular tone is almost certain to have the same influence on the muscle fibers in the walls of the arteries and veins.

Each step toward myocardial degeneration, cloudy swelling, hypertrophy, perhaps at its side atrophy of the fibers, fatty change, hyalin metamorphosis, replacement fibrosis, calcification—all of these represent incapacity through inability to sustain tone. In addition there is likely to be a diminished supply of an infected and chemically altered blood. It is little wonder that tone and accomplishment are both impossible under these conditions.

TOXIC PARALYSIS OR PARESIS OF THE CARDIAC MUSCLE AND NERVE FIBERS

There are many indications that either or both the vagus and the sympathetic cardiac systems of nerves may be embarrassed or completely paralyzed by the toxins of the acute infectious diseases. It is well known that drugs that ordinarily affect and stimulate the vagus branches to the heart fail to exert their usual influence under the shadow of an active toxemia. Physiologic conditions are abnormal. More and more frequent are the reported instances of so-called functional heart-block in pneumonia, in rheumatism, in syphilis, and in other acute toxemias. In some of these instances the lesion has been shown to be a round-cell infiltration of the auriculoventricular connecting fibers.

As long ago as 1905 Mackenzie[5] called attention to the occurrence of partial heart-block in influenza. In other temporary cases in which there has been clinical recovery, the disturbing influence has appeared to be wholly toxic, and has seemingly been exerted through both the muscular and the nervous tissues. In one of Routier's rheumatism cases[6], recently reported, a heart-block disappeared under the influence of atropin; in a second case, one of pneumonia, without treatment. In a case of heart-block in rheumatism reported by Gosse,[7] the loss of function persisted, in spite of treatment, for eighteen days. Occasionally temporary heart-block is noted in a case which at length comes to necropsy, when there appears to be an entire absence of explanatory and causative lesion. It would seem, however, that a more diligent search might discover evidences that escape the ordinary observer.

Auricular fibrillation and flutter are not rare phenomena in the toxic heart. While not essentially toxic disturbances, as is demonstrated by their appearance in a dying (normal) heart after removal from the laboratory animal's body, there is no question that the toxins of the acute infectious diseases may and do bring the same conditions to pass. Sutherland[8] has just published an interesting study of auricular flutter in acute rheumatic carditis, and of the clinical signs indicating the presence of this condition.

ENDOCARDITIS (VALVULAR AND MURAL)

Rheumatism (tonsillitis, arthritis, chorea) and syphilis are recognized as the two most frequent causes of valvular heart disease. We are, however, just now in the transition stage with respect to the meaning of "rheumatism," and its relation to the streptococcus in general, to the *Streptococcus viridans* in particular, and to many other forms of subacute and acute bacterial endocarditis. Typhoid fever, pneumonia, influenza, diphtheria, tuberculosis, occasionally involve the valves, but show a marked predilection for the myocardium. Scarlatina very frequently is found to have antedated a valve lesion that appears to have no other explanation. If scarlatina is finally pigeonholed in the category of streptococcic infections, we shall have the needed explanation for this probable etiologic sequence.

We seem bound in the near future to discard the term "rheumatism." Certainly no one has the unscientific privilege of believing, and still less of asserting, as did one critic who wrote to me recently of a number of cases of valvular disease with an entire absence of rheumatic history (arthritis, sore throat, tonsillitis or chorea), "Your cases were rheumatic, I believe,"—I repeat, no one has the privilege of throwing every etiologically obscure case of valvular disease into the rheumatic dump-heap, at least until the pale spirochete has been proved absent, and probably not then. We can and should catalogue the myocardial as well as the valvular lesions that have heretofore been ascribed to "rheumatism" under their proper etiologic classification. Whether or not we shall eventually limit the meaning of the term "rheumatism" to hearts showing Aschoff's nodules remains to be determined. Acute syphilitic lesions of the valves or of the myocardium may, indeed, often be diagnosed by the presence of the *Spirochaeta pallida*. In old and chronic lesions this diagnostic help may not be afforded. The etiologic significance of the other acute infections mentioned above can be ascertained only by a careful clinical following of the heart during the acute attack, and by a comparison with its known previous state.

Whatever the causal factor in a given infectious disease, the endocardial lesion follows one of two or three lines. Either it begins and persists as an inflammatory change in which fibrosis is the ultimate outcome; or vegetative deposits and growths appear; or, finally, the vegetative and ulcerative processes of malignant endocarditis manifest themselves. Any one of the infections may initiate any of the three types of mural or valvular endocarditis, sclerotic, vegetative or ulcerative. Rheumatism and the typically acute diseases (except gonococcemia) tend to the production of the vegetative, recurrent type. Syphilis, on the other hand, leans toward sclerosis from its beginning to its final deformity. More and more clinicians are to be found who believe that in the absence of a known causative factor a valvular lesion of either of the two more chronic types should be suspected of being syphilitic until proved due to some other etiologic influence. In the presence of fibrous arteries in a young person the presumption becomes almost a certainty.

The endocardial lesion may consist of a filmy lymph deposit on the line of junction of the cusps; or it may result in the stoppage of the passageway by a projecting mass; or the cusps may be shriveled and warped and noduled out of shape and position; or, finally, ulcerative processes may have eaten their way through. Endocarditis may thus constitute a mere baptism, or it may mean a destructive involvement that stops short only when the tissues are consumed.

PERICARDITIS

As the pericardium enjoys the same general blood-supply as the myocardium and the valves, there is little chance of its escaping involvement by any and every infectious process that is blood-borne. Many writers and teachers are skeptical regarding the occurrence of a primary pericarditis. None questions the frequency of the toxemic or of the bacteriemic forms. Indeed, contiguity to the pleura as well as to the myocardium would almost render a primary form of pericarditis unnecessary to explain the origin of the vast majority of instances. Conditions are so favorable to a direct extension of an inflammatory process from one structure to another that this would seem the natural order of events. As a matter of fact, it is an exceptional case of fatality from the acute infectious diseases that fails to show at the necropsy definite evidence of pericardial inflammation. Often a mere fibrinous patch, more frequently also an excess of pericardial fluid, rarely a purulent effusion, it would be almost an anomaly were the pericardium to be found free, when the structures so intimately associated with it are involved.

Pericarditis occurs in children at an early age. Blechmann[9], in studying 500 cases of pericarditis in the London Hospitals, found that 25 per cent. of all occurred earlier than the fifth year, and 50 per cent. before the fifteenth year. The toxemias in rheumatism and in the pneumonias are the most frequent causes, though all of the eruptive diseases contribute to the total. Heretofore rheumatism has been cited as the infection most active in the causation of pericarditis. When, however, we finally learn to discriminate between true rheumatism and other septic arthritides—when, indeed, we discover just what true rheumatism is—we shall probably find that it is not the cause of many cases that have been included under its name. In a series of sixty-seven cases of serofibrinous pericarditis in the University and Bellevue Hospital, Brooks[10] found twenty-six secondary to pneumonia, which led the field as a causative factor.

In early adult life nephritis begins to contribute a very positive percentage of cases. Many of the mediastinal inflammatory conditions also exert an influence It must not be forgotten that the heart and the pericardium rest posteriorly on the esophagus and aorta, and that anteriorly the pericardium is intimately attached to the pleura. In a considerable number of instances of both acute and chronic tuberculosis the pericardium is found at the necropsy the seat of active tuberculous disease. Scarlatina, cerebrospinal fever, influenza, erysipelas and syphilis all contribute their quota—and bear out the assertion that whatever infests the blood-stream finds it difficult to pass the pericardium by.

MUSCULAR AND VALVULAR INSUFFICIENCIES WITH CARDIAC DILATATION

Only a word need be added with regard to the direct etiology as contrasted with the symptomatology of the insufficiencies (muscular and valvular) of the hearts in subjects suffering from the acute infectious diseases.

We were all taught, and later at some time no doubt began to teach, that the dilated heart usually is incompetent as the result of the misbehavior of some one valve or valves. In fact, in the study of both the acute and chronic heart lesions we have been led to overemphasize the importance of the valvular abnormality and to ignore in a measure the significance of the covering and substance of the organ. We forget that the same condition or infection has caused both the endocarditis and the myocarditis. To-day it would be well for us all to take up again the study of the histopathology of the heart muscle, not with a view to exaggerating the frequency of cardiac disease, but of placing and locating the point of attack, and appraising the etiologic bearing of the infections to acute involvements of the myocardium.

There is an unfortunate tendency among heart students to teach the needlessness of fear of athletic overstrain or damage to a heart which shows no frank signs of cardiac disease. In the light of this study it would be well worth a young man's time and trouble to have his physician inquire into his past history with reference to the acute infectious diseases, and a possible latent structural insufficiency of the cardiac muscle. We constantly hear of young athletes being hurried from their convalescence from a tonsillitis, or even a typhoid fever, into training, and thence into an eight-oared race or a football match. More than once I have personally come into conflict with a medical director of a school or college who appeared willing to permit some young giant, though already suffering from air hunger and cardiac arhythmia evident to the patient, to engage in athletics no less strenuous than a football contest or a cross-country run.

TREATMENT AND PROGNOSIS

What is the treatment and what the prognosis of a carditis such as one must expect in an acute infectious disease? I would suggest in a word for the acute illness the most perfect possible rest, and the saving of every unnecessary contraction of an organ which we unfortunately cannot ever put to sleep. At the beginning of treatment, an empty, and, for a little time, an "as nearly as possible" sterile gastro-intestinal tube will be the second essential, instead of the frequent attempt to overnourish and feed. Drugs, except opium and possibly atropin, will be of questionable value. If employed at all they should be such as are calculated to subdue and quiet overeffort, rather than incite and excite a lame organ to further exertion. No drug will decide the issue between cardiac competence and collapse. It may be that even the cardiac sedatives and tonics had better be omitted. The most difficult period for the physician will be the convalescence, and the year following the acute illness. If we would conserve the heart muscle and its endocardium it will be of prime importance that all localized foci of infection should be removed from the body. We are just beginning to appreciate the fact that diseased tonsils and adenoids invite a heart lesion, a pulmonary tuberculosis or a pneumonia; that pus tubes or an infected prostate may underlie malignant endocarditis or a joint rheumatism; and that a grumbling appendix may be the cause of arteriosclerosis, myocardial degeneration, arthritis deformans, or varicose veins. In short, it is not safe from any point of view to ignore a chronic focus of disease.

Very gradual must be the progress in dispensing liberty and freedom to a convalescent from an acute infection in his venture back toward a normal life. Very thorough and intelligent must be the physician's test of the heart's capabilities before the patient is turned over completely to his own direction and guidance. Long after the acute attack has been forgotten the heart muscle may betray a latent disability that has lingered and escaped suspicion. Fortunate the man or woman who enjoys a full convalescence and a life of uninterrupted health following the damage sustained by the cardiac structures in the infectious diseases of an earlier age.

THE INTRADURAL ADMINISTRATION OF MERCURIALIZED SERUM IN THE TREATMENT OF CEREBROSPINAL SYPHILIS *

CHARLES METCALFE BYRNES, M.D.
Instructor in Clinical Neurology, Johns Hopkins University
BALTIMORE

The subject of syphilis in general, and syphilis of the central nervous system in particular, is at present in a transitional state; and it is, therefore, desirable to formulate a tentative classification of the disorders which are to be included under the title of this paper.

In its broader sense, the term "cerebrospinal syphilis" may be so construed as to include every pathologic process within the central nervous system which is of a specific nature. If this broader meaning is adopted, it should be clearly understood what anatomic limitations are to be placed on the central nervous system. Histologically, it could not be said to include more than the true nervous tissue, since the cerebrospinal vessels and meninges, although integral parts of the central nervous system, are not, strictly speaking, neurologic units. Pathologically and clinically, they are, however, quite inseparable; and experience has taught that, for practical purposes, syphilitic affections of the cerebrospinal or central nervous system cannot well be studied independently of the meninges and blood-vessels.

Since these structures may be involved independently or collectively, it has been the custom to treat syphilis of the central nervous system under the following subdivisions: (1) meningitis, secondary or tertiary; (2) cerebrospinal syphilis, which has further been divided into three types, endarteritis, meningomyelitis and gummatous infiltration, and (3) the two parasyphilitic disorders, tabes dorsalis and general paresis. Continued reports on the Wassermann reaction and the recent studies of Noguchi seem to indicate that these so-called parasyphilitic diseases can now be regarded as instances of true syphilitic affections of the nervous system. Consequently, when a diagnosis of cerebrospinal syphilis is made, it is obvious that a multiplicity of pathologic and symptomatic states may be included.

Recent observations by Swift and Ellis[1] and similar personal experiences have led me to believe that it will be helpful to designate the endarteritic group of cases in a separate classification distinct from specific diseases of the cerebrospinal system. It has been observed, in the majority of cases of syphilis in which the neurologic symptoms indicate a vascular disturbance, that the spinal-fluid examination is quite normal. The cell count is only slightly, or not at all, increased, and the fixation test is frequently negative; but the Wassermann serum reaction is generally positive. In my series of cases, these observations have been so uniform that not infrequently it can be predicted, with some assurance, that the spinal-fluid examination will be within normal limits. Naturally, the accuracy of one's prediction will depend somewhat on his ability to distinguish the vascular nature of the affection.

These observations and the demonstrations of the specific organism in the so-called metasyphilitic diseases, together with their determining influence on the form of therapy to be employed, have suggested to me the following classification of syphilitic affections of the central nervous system:

1. Syphilitic meningitis, secondary and tertiary.
2. Cerebrospinal syphilis, including all specific affections in which the nervous tissue itself is directly affected, such as meningomyelitis, gummatous infiltration, tabes dorsalis and general paresis.
3. Cerebrospinal syphilitic arteritis.

To the clinician, this comprehensive use of the term "cerebrospinal syphilis" can hardly be more than confusing unless the particular variety is clearly stated. It is therefore advisable to continue the use of the older terminology, with the understanding that parasyphilis has only clinical significance, and that syphilitic arteritis of the cerebrospinal vessels probably exists without direct invasion of nervous tissues.

With the specific nature of these diseases more clearly established, it was hoped that the use of Ehrlich's new preparation might be the means of securing brilliant therapeutic results. Unfortunately, at first, it was just this class of cases which was thought to offer particular contra-indication to its administration. The hopelessness, however, of many cases seemed to justify the assumption of reasonable risk; so that, in time, this early objection was overcome and salvarsan began to be widely used in all forms of syphilitic nervous affections. While in some instances the improvement was remarkable, there were many cases in which the results were disappointing.

This failure to secure equally promising results in diseases of the central nervous system was not long

* Read before the Philadelphia Neurological Society, Oct. 23, 1914.

[1] Swift and Ellis: The Cerebrospinal Fluid in Syphilis, Jour. Exper. Med., 1913, xviii, 162.

in stimulating more diligent efforts to ascertain the cause of this failure and establish, if possible, a more successful mode of therapy. Two probable explanations were readily suggested. Either irreparable changes had taken place in the nervous system, or the drug failed to reach the seat of infection. The first explanation was unsatisfactory, and destined to discourage further hope of progress in this direction. There is, no doubt, an incipient stage from the period of invasion of the central nervous system to the beginning of destructive changes when it might be hoped to arrest the disease by efficient therapy. Although the period of invasion and duration of the incipient stage are undetermined, it has been observed that even in the earliest manifestations of nervous symptoms, intravenous administration of salvarsan is often apparently ineffective. It seemed, then, that the second explanation offered greater encouragement for further investigation; and the first noteworthy contribution in this direction was made by Swift and Ellis[2] when they introduced a method of administering salvarsanized serum directly into the subdural space.

The technic of this method is now well known and the method itself, which was at first received with some skepticism, has lately become quite generally adopted. Unhappily, just as intraspinal therapy appeared to be gaining recognition, it received a severe blow from the unfortunate experiences on the western coast. Whether this was a determining factor or not, it appears to be true, at present, that the earlier enthusiasm regarding this form of intraspinal therapy is somewhat diminished. While the real value of the method has been questioned, I believe there can be little doubt that some form of direct therapy is desirable. If the infection is localized within the central nervous system, and it can be demonstrated that drugs given by the usual methods do not reach the seat of infection, it is obvious that the adoption of a direct method of administration is to be encouraged.

Numerous parallel studies on the Wassermann reactions in the serum and spinal fluid, together with the increased globulin and lymphocytes in the spinal fluid, seem to indicate that the central nervous system not infrequently shows evidences of specific infection, while the extraneural tissues, as represented by the negative Wassermann reaction in the blood, have apparently escaped. With a local infection so isolated from the systemic circulation that its nature could not be determined by the usual serum reactions, it was logical to assume that substances introduced into the circulating blood might not reach the seat of infection.

The studies of C. D. Camp[3] on the spinal fluid of seventeen patients who had received intravenous doses of salvarsan established the fact, in his case at least, that no evidence of the drug could be detected in the spinal fluid. The fluid was examined at variable intervals after treatment, and in only one case, after large and repeated doses, was there any evidence of arsenic. Others, however, have reported its presence in very minute quantities. Since the physiology of the spinal fluid and its relation to the vascular system is still undetermined, any explanation of these negative findings must be more or less problematic. As a matter of fact, such observations awakened a more lively interest in a direct form of therapy and encouraged my belief that the Swift-Ellis method is a step in the right direction.

While my earlier experiences with this method were most encouraging and were quite parallel with those recorded by Swift and Ellis, continued observation soon taught me that their method, although most promising, is not all that is to be desired. From a clinical and laboratory point of view there were unquestioned evidences of its usefulness, and fortunately, in my experiences, no alarming consequences.

The manner in which salvarsanized serum was supposed to be effective was an early subject for discussion. It was thought that the arsenic had undergone some change within the circulatory system which rendered the serum preparation spirocheticidal. On the other hand, those who were skeptical questioned the efficacy of the method altogether and maintained that the improvement in clinical symptoms was entirely due to the intravenous administration; while the reduced cell count and globulin and fixation tests in the spinal fluid could be accounted for by the withdrawal of spinal fluid and dilution of the remaining portion by the injected serum.

However this may be, it does not require extensive mathematical knowledge to understand that 12 c.c. of serum (the original amount advised by Swift and Ellis) removed from a patient who has received only 0.6 gm. of salvarsan must contain an infinitesimal amount of either the altered or original arsenical preparation. This, it seems, is the most forceful argument against the adoption of this form of intraspinal therapy, and the subject is admirably treated in a current article by Sachs, Strauss and Kaliski[4] From the chemical analyses of Benedict on ten specimens of blood removed from fifteen to forty-five minutes after intravenous injection of salvarsan, these authors have made some interesting calculations. Only from 0.00004 to 0.0001 gm. of metallic arsenic could be detected in 20 c.c. of whole blood, and from these figures it was estimated that blood removed three-quarters of an hour after administration of salvarsan contained practically no free arsenic in the serum.

After almost a year's experience with the original Swift-Ellis method, it occurred to me that more effective action might be secured if a larger quantity of some specific drug were introduced into the subdural space. Even a hasty review of the literature soon taught me that the direct introduction of unchanged salvarsan in any appreciable quantity could not be done without serious risk to the patient. Wechselmann,[5] and later, Marinesco,[6] had used neosalvarsan in aqueous solutions, but the results were doubtful and the reactions severe. Within the same year, Ravaut[7] began the use of unchanged neosalvarsan intraspinally, and a few months later Marie and Levaditi[8] made similar experiments in the treatment of general paresis, with disappointing consequences. Subsequently, Ravaut[9] improved his technic slightly by using hypertonic solutions in freshly distilled water, by which he asserted that he obviated the unpleasant irritative effects of the injection. In April of the same year,

[9] Ravaut: Ann. de méd., 1914, i, 49.

Wile[10] introduced this revised technic in America and used it without unpleasant results in two cases. He injected from 1 to 4 drops of a 6 per cent. aqueous solution of neosalvarsan intraspinally (equivalent to from 3 to 12 mg. of neosalvarsan). It has been further suggested by Marinesco and Minea[11] that the arsenical preparation be added in vitro to the patient's serum, and they report the adoption of this method in twenty cases, but the results were, on the whole, discouraging.

The whole question of intraspinal arsenical therapy is very wisely and cautiously summarized in an editorial[12] of The Journal almost a year ago, which, in my opinion, is quite acceptable at the present time. The instability of these complex arsenical preparations and their irritative and toxic properties make their direct introduction into the dural sac an extremely hazardous procedure, and my desire to make further studies in this direction was not encouraged by the experience of others.

It was no new departure to think of introducing mercury into the subdural space. Irrigation of the spinal canal with 1:30,000 mercuric chlorid solution had already been practiced as a postoperative measure, and later, Ravaut[7] reported the injections of mercurial salts into the dural space for the treatment of cerebrospinal syphilis. His technic, however, and exact dosage are not clearly stated, and the laboratory studies are incomplete. He reports two cases. The first was treated by intraspinal injection of 2 drops of a 1:1,000 mercuric chlorid solution. The only unpleasant after-effect was slight increase in headache. Three days later the patient left the hospital and did not return for further study or treatment.

The second case, which was treated with mercuric cyanid, received intraspinally 2 drops of a 1 per cent. solution. The cyanid was chosen because it was thought to be a very active salt, rich in mercury, and from animal experimentation less apt to produce local irritation because of its lowered coagulative properties. The reaction in this instance, however, was pronounced. A few minutes after administration the patient complained of pains and cramps in the legs. These were followed by severe muscular contraction which began in the feet, ascended to the trunk and arms and later involved the whole body. Trismus was pronounced. The contractions were of five or ten minutes' duration, and on the following day most of the irritative symptoms had subsided. An examination of the spinal fluid four months later showed considerable reduction of the lymphocytes and a negative Wassermann.

These discouraging results with the direct introduction of mercurial salts convinced me that they were scarcely less toxic, in appreciable doses, than the more unstable arsenical preparations. If mercury were to be used at all it is evident that a preparation must be obtained which is therapeutically active, and at the same time possesses comparatively low toxicity and local irritative action.

The fact that many patients who came to me for the Swift-Ellis treatment had already received thorough courses of mercurial therapy suggested that they might be receiving along with the salvarsanized serum a mildly impregnated mercurialized serum.

A series of experiments was then begun in which fifteen patients suffering from syphilitic diseases of the nervous system were divided into three groups of five each. The several groups were given active mercurial treatment by the following methods: The first group received inunctions, the second daily intramuscular injections of the biniodid in oil, and the third mercuric chlorid and potassium iodid by mouth. All were carried to the point of saturation, when blood was withdrawn and serum obtained for chemical analysis.

The serum was sent to Drs. Penniman and Browne, analytic chemists of Baltimore, with the request for a quantitative estimate of the mercurial content. Specimens of spinal fluid were also obtained for similar analysis.

On completion of the chemical analysis, Dr. Browne sent the following report on technic and results: The mercury was extracted and converted into mercuric chlorid and the quantity estimated according to the well-known Nessler color reactions. While the analysis showed slight variations in the amount of mercury present, in general, these investigations would indicate that (1) the serum of patients treated by inunctions showed a slightly higher mercurial content than that from the other two groups; (2) the average mercurial content of serum from all three groups was approximately 0.0000059 gm. per cubic centimeter, and (3) the spinal fluid in two instances showed only a questionable trace of mercury which was too small to be estimated. The report is concluded with the following caution:

> The difficulties in estimating such minute quantities are so great that I wish to remind you that these figures must not be accepted as absolute. In an endeavor to find the limits of accuracy in this work, I made a solution of blood albumin and added a known quantity of mercury (0.000058 gm.). I recovered from the solution by this method 0.000047 gm., or 80 per cent. of the amount taken.

While it would be absurd to entertain the idea that a patient's serum could, by this means, be sufficiently impregnated with mercury to render it of therapeutic value, these analyses convinced me that mercury is present in the circulating blood in amounts approximately equal to the arsenical content after salvarsan therapy, and that in the majority of cases it is not detected in the spinal fluid. Evidently, then, many patients who were being treated with salvarsanized serum were receiving at the same time a serum of low mercurial content, but in too small amounts to possess any therapeutic value or furnish any information as to its local action and toxicity; and it seemed reasonable to conclude that a preparation of mercury similar to that supposed to exist in the circulating blood would offer many advantages for intraspinal administration.

When an inorganic salt of mercury comes in contact with protein matter a coagulative process occurs, in which the insoluble albuminate of mercury is formed; and the occurrence of this reaction led me to believe that it might account for some of the unpleasant symptoms following the direct introduction of inorganic salts of mercury into the subdural space. If mercury exhibits this affinity for the protein molecule it would seem advisable to make use of a preparation in which this affinity is already satisfied. The albuminate, which is supposed to exist in the circulating blood, seemed to answer these requirements. Although its toxicity may not be less than that of the inorganic salts, since definite knowledge concerning the physical state of the albuminate ion is wanting, it was thought that it might be less irritating, and especially so if administered in a serum menstruum.

[10] Wile, U. J.: The Technic of the Intradural Injections of Neosalvarsan in Syphilis of the Nervous System, The Journal A. M. A., April 11, 1914, p. 1165.

[11] Marinesco and Minea: Bull. de l'Acad. de méd., 1914, lxxviii, 259.

[12] Deaths Following Injection of Neosalvarsan in Los Angeles, editorial, The Journal A. M. A., March 21, 1914, p. 935.

Since the manufactured albuminate on the market is difficult to obtain, unstable and insoluble, it was decided that more satisfactory results might be obtained by adding a mercurial salt directly to human serum. The precipitated albuminate which is at first formed is readily soluble in an excess of albumin, so that on the further addition of serum a perfectly clear solution is obtained. By fractional precipitation, it was determined that approximately 0.022 gm. (⅓ grain) of mercuric chlorid, in solution, may be added to 2 c.c. of serum before precipitation is complete, and that it is necessary to add 4 c.c. more of serum in order completely to dissolve this precipitate. In other words, 6 c.c. will hold in solution 0.022 gm. (⅓ grain) of mercuric chlorid converted into the albuminate.[14]

Obviously, then, a perfectly clear solution of mercury albuminate in blood-serum can be obtained in which the mercurial content is larger than that desired for therapeutic purposes. Consequently, I determined to make use of such a serum for intraspinal administrations. At first the dose of mercury was extremely small and was determined according to body weight, the average tolerance for mercury when administered intramuscularly, and the proportion between the volume of circulating blood and spinal fluid. By cautiously increasing the dose of mercury, it was found that 0.0013 gm. (1/50 grain) of mercuric chlorid and even 0.0026 gm. (1/25 grain) could be safely administered when added to the prepared serum. Perhaps even larger quantities may be given, but I have found the smaller amounts quite effective.[13]

TECHNIC

The technic for the preparation and administration of the serum is similar to that employed in the Swift-Ellis method, except that no drug is administered before withdrawing the blood.

1. Sufficient blood is withdrawn to yield from 12 to 30 c.c. of serum. The larger amount is obtained if concentrated serum is to be used. After the blood has coagulated the serum is pipetted, and if necessary,
2. Centrifugalized for twenty minutes.
3. If diluted serum is to be used, to 12 c.c. of the centrifugalized specimen is added 1 c.c. of a solution of mercuric chlorid in freshly distilled water so made that each cubic centimeter contains 0.0013 gm. (1/50 grain) of mercuric chlorid.
4. To the serum thus prepared is added sufficient quantity of normal salt solution to make a total volume of 30 c.c. If the concentrated serum is used this step is omitted.
5. It is heated at 56 C. (132.8 F.) for half an hour, and
6. Administered, by gravity, at body temperature.

Since the desired amount of mercury is readily soluble in the diluted serum I can see no special reason for employing the concentrated preparation.

In administering the serum, I have adopted the method followed by Swift and Ellis. With the patient lying in bed, lumbar puncture is done, pressure readings are made, and spinal fluid withdrawn until the pressure falls to 30 mm. The serum is then administered and the foot of the bed elevated about 8 inches for half an hour.

CLINICAL RESULTS

At the present writing I have the records of thirty-two patients with syphilis of the nervous system who have been treated by this method. The records have been collected from my private practice and from the Sheppard and Enoch Pratt Hospital (Towson, Md.) where, through the kindness of Dr. E. N. Brush, permission was obtained to have Drs. Sargent and Asper of that institution use this technic on the material at their disposal.

Of the 32 cases there are 13 of tabes dorsalis, 2 of taboparesis, 3 of cerebrospinal meningomyelitis and 14 of general paresis. In general, the cases of tabes and meningomyelitis have shown the most marked improvement although, in a few instances, general paresis has been distinctly benefited. Since it would be just as instructive, and certainly less tiresome, to the reader, to make general deductions from the series of cases as a whole, I shall not burden him with a detailed account of individual cases.

The reaction following the administration of mercurialized serum is usually mild. There is some pain in the legs for six or twelve hours, slight nausea, rarely vomiting, and a moderate rise of temperature. All of these symptoms generally subside within thirty-six hours. I have not observed the sphincter disturbances sometimes seen after the use of salvarsanized serum, nor has there been any evidence of renal disturbance or other untoward symptoms.

The improvement in clinical symptoms has been similar to that observed in the Swift-Ellis method. In most instances of locomotor ataxia, there has been decided relief of the pains, the gait has improved, and gastric symptoms have been distinctly alleviated; in others, there has been little or no change in the clinical condition. A tabetic and a patient with taboparesis showed such marked improvement that they deserve brief mention. When first seen, the tabetic was annoyed by bladder disturbances, slight sexual disorders, and inability to walk without assistance. After four treatments all symptoms were markedly improved, and I have lately heard that he is now conducting a profitable business and is the father of a healthy child. In the case of taboparesis, in which there were such marked mental features that the patient could not be left alone, it was decided to try first a thorough course of mercury by intramuscular injections. When the limit of tolerance was reached, there was practically no change clinically, and it was decided to begin intraspinal therapy with mercurialized serum. Following the first administration there were evidences of improvement in the mental state and this improvement continued after each treatment. In all, five intraspinal injections were given, and on the patient's discharge from the Sheppard and Enoch Pratt Hospital Dr. Sargent made the following note: "The patient's mental condition is practically normal, all grandiose ideas have disappeared, expansiveness is gone, the gait is improved, and he has gained 19 pounds in weight." Six months later the patient was seen by Dr. Hamburger and myself, and his mental condition was so clear that it was decided not to commit him to an insane institution, where his family wished to send him because of the attention required on account of his tabetic symptoms.

---

[13] After this article was prepared for publication, a letter was received from Mr. Campbell, of the H. K. Mulford Co., containing a report of Dr. Pittenger's experiments in their laboratory. At my suggestion Mr. Campbell kindly directed that studies be made on the toxicity and local irritative action of mercurialized serum. It has been determined that by intravenous administration this serum is as toxic as the inorganic salts of mercury, but when administered intradurally it can be given in much larger doses.

[14] These proportions are only approximate. No doubt a much larger quantity of mercuric chlorid may be added.

The spinal fluid has, in every instance, shown a marked decrease in the cellular elements, and in many cases, the diminution has occurred more rapidly than is observed after the use of salvarsanized serum. The globulin is in general diminished, but the Wassermann reaction, as in the use of salvarsan, appears to be less readily affected. In the thirty-two cases a negative reaction was obtained in only twelve. This low percentage may be accounted for by the fact that the number of treatments was determined largely by the cell count and clinical symptoms; and since these usually showed evidences of improvement after relatively few treatments — usually five — further treatment was not insisted on. Perhaps a more prolonged course might have increased the percentage of negative Wassermann tests.

CONCLUSIONS

1. While it is not declared that mercurialized serum alone is the only treatment that is necessary in syphilis of the central nervous system, I believe it is equally, if not more, efficacious than salvarsanized serum in the local treatment of these diseases.

2. The immediate reactions following its administration are, in general, not so severe as those after the use of salvarsanized serum, and the cell count in the spinal fluid appears to be more quickly reduced.

3. Since preliminary medication is not required, the blood may be obtained at any time; and because of the greater stability of the mercurialized serum it may be prepared at leisure and kept in sealed flasks until it is convenient to administer it.

4. In certain cases of cerebrospinal syphilis in which the serum Wassermann is negative but in which there are all the indications for intraspinal treatment, it has impressed me as unfortunate that the patient had to be subjected to the discomforts of an intravenous administration of salvarsan merely for the purpose of securing a preparation for intradural injection. This objection does not arise in the use of mercurialized serum. It is true that in many cases both the blood and spinal fluid show evidences of infection, and in such instances I have not felt that the intravenous dose of salvarsan could justly be withheld, so that I have frequently given the combined salvarsanized and mercurialized serum intraspinally.

5. Owing to the greater stability of the mercurialized serum, it is hoped that a method may be devised by which a permanent preparation can be dispensed in sealed ampules and thus simplify the whole technic of intraspinal therapy. While it may be unwise to entertain the idea of using a foreign serum, it is not unlikely that human serum may be obtained in sufficient quantities for this purpose.

Nativity of Parents and Infant Mortality.—Investigation of deaths of infants from so-called congenital disease, including prematurity, congenital debility, convulsions, malformations and injuries at birth, by the Bureau of Child Hygiene of New York City disclosed a definite relation existing between the proportion of congenital deaths and the nationality of the parents. Only three nationalities were considered as the proportion of the others was too small to be of consequence. The Italian and Russian-Austrian proportions of deaths are very low as compared with their proportions of births, while the United States and "All Others" are relatively high. The percentage of congenital deaths among the United States group is 32.3; all others, 43.6; Italians, 14.6; Russian-Austrian, 18.5.

A MORPHOLOGIC AND CHEMICAL STUDY OF THE DOUBLE REFRACTIVE FATS OF THE ADRENALS IN DELIRIUM TREMENS *

EDWIN F. HIRSCH
CHICAGO

Kaiserling and Orgler[1] were the first investigators to call attention to the presence of anisotropic droplets or liquid crystals in the cortex of the human adrenal glands. Herrmann[2] later studied a small number of human adrenals with regard to their content in the doubly refractive substance, and reports it uninfluenced by age, but diminished by wasting diseases. He observed its entire absence once in the adrenals of a 70-year-old woman dying from miliary tuberculosis, and again in the glands removed from a body with long-continued, chronic lung phthisis. The small number of glands studied was not sufficient, however, to permit drawing conclusions regarding the causal relationship between disease and the absence of the anisotropic droplets. White[3] also merely reports the presence of doubly refractile droplets in the adrenals removed from thirty individuals dying from various diseases. Kawamura[4] observed the anisotropic substance in a finely divided form in the cortex of adrenals removed from fetuses and children up to 10 years of age. The abundance of this, he records, is not influenced materially by chronic and acute diseases, but is diminished markedly by sepsis and alimentary intoxications. Kawamura observed no diminution of the doubly refractive substance in disorders of the vessels, obesity, marasmus, tumors and inanition, but on the contrary, in some of these conditions an increase. He confirms Herrmann's observations on its diminution in chronic tuberculosis, and that age does not seem to influence its amount. A diminution of these droplets is recorded by Kawamura in sepsis, typhoid fever, diabetes, and once in chronic nephritis. Weltmann[5] records their diminution in the adrenals removed from persons dying with septic diseases, typhoid fever, severe infectious enteritides, purulent peritonitis, frequently in croupous pneumonia, ulcerative carcinoma, and cavernous phthisis; on the other hand, he found them abundant in atherosclerosis, cirrhosis of the liver, chronic nephritis, generalized passive congestion, cerebral hemorrhage, and encephalomalacia, as well as in subacutely progressing infections. A complete absence of the doubly refractive substance is reported by Mulon and Porak[6] in the adrenals removed from the body of a patient dying with Huntington's chorea. A relatively smaller amount of the adrenal lipoids was found by Landau[7] in phthisis, septic processes, and with many tumors.

Practically all investigators agree in considering the doubly refractive droplets present in the adrenals as lipoids, or, more exactly, esters of cholesterol. According to Kawamura there may be other doubly refractive spheroliths present in fresh tissues, such as the globules in the uric acid infarcts, in part the psammomas, and the prostatic corpora amylacea. These, of course, are not lipoids. Moreover, doubly refractile globules occur in fatty livers, in cloudy swelling of the liver, and have been observed in teased preparations of the central nervous system, especially in diseased softened regions together with myelin droplets or globules, as well as in numerous other pathologic retrogressive processes. In none of these, however, do the droplets lose their double refrangibility with heating. Kawamura summarizes the optical properties of the anisotropic droplets in question as follows: In a fluid state they are doubly refractive; a property lost on heating, to be assumed again with cooling. In tissues fixed with 10 per cent. dilution of liquor formaldehydi they appear as needle-like crystals which are converted by heat into doubly refractive droplets. The relation between the droplet doubly refractive substance in fresh tissues and the crystalline in fixed preparations, he states, is always constant and equal. The same relation is also true on changing the crystalline form into the globular by heat. In the examinations to be mentioned presently these observations by Kawamura have been confirmed repeatedly.

Rosenheim and Tebb[8] analyzed chemically the lipoids from the adrenal and isolated a mixture of fatty acids and cholesterol esters, as well as small amounts of sphingomyelin and phrenosin. Adami and Aschoff[9] sought to determine the chemical nature of these anisotropic droplets by preparing substances artificially with doubly refractive properties, and observed that the following may contain doubly refractive myelin figures, and sometimes also droplets: (1) phosphatids, among which is lecithin; (2) soaps of the fatty acids; (3) cholesterol esters; (4) solutions of cholesterol in phosphatids, in fatty acids and in fats; (5) solutions of cholesterol esters in fats. Of these, only the cholesterol esters easily formed permanent emulsions which contained doubly refractive droplets. Kawamura pursued the same method of investigation on a large number of chemically pure lipoids, as well as with artificial lipoid mixtures. Aside from the cholesterol esters, he observed doubly refractive globules in sphingomyelin and phrenosin isolated both from the brain and from the adrenals. Also with cephalin-cholesterol and cephalin-cholesterol-oleic acid mixtures, lecithin, and sodium oleate. The cholesterol-fatty acid mixtures tend to form myelin, a reaction dependent on the dissolved cholesterol, for the doubly refractive properties appear only with a relatively rich cholesterol content. Cholesterol-glycerol mixtures, glycerol esters, cholesterol-palmitic acid esters, myelin, the fatty acids, soaps, and cephalin have no doubly refractive properties.

In the examination of the bodies of persons dying from delirium tremens, Dr. E. R. Le Count, one of the coroner's physicians in Chicago, found alterations so regularly in the cortices of the adrenals that it was decided to ascertain, if possible, the reason for such changes. The changes consist in a more or less striking diminution of the yellow color normally present in the cortex. This diminution is frequently a narrowing of the yellow, band-like cortex combined sometimes with its irregular disappearance, producing an uneven yellow edge bordering the medullary region into which the substance of the medulla apparently extends, sometimes reaching entirely to

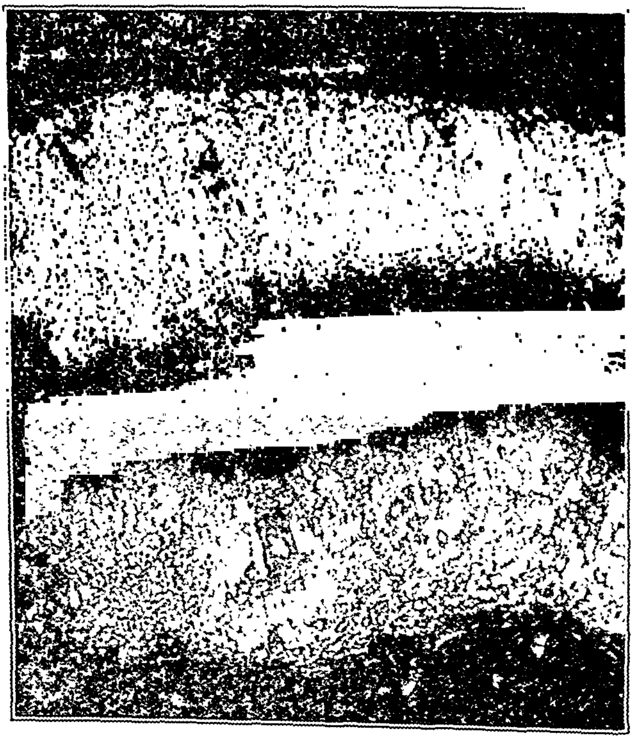

Fig. 2.—Same field illustrated in Figure 1 with the Nicol prisms crossed; the light portions represent the distribution and abundance of the double refractive lipoids; × 38.

the capsular margin. In very marked instances, the entire cortex assumes a reddish-brown color with only occasional areas of yellow distributed at irregular intervals, or there may seem to be an entire absence of all the yellow substance. These changes are grossly very interesting, and so regularly encountered in delirium tremens that when they are absent, as a rule, some other influence than simply the poisonous action of the alcohol manifested as delirium tremens is found contributing to death.

The adrenal glands removed for the purpose of study were weighed after the perirenal fat had been dissected away carefully, and then fixed in 10 per cent. dilution of liquor formaldehydi. After a few days, thin transverse segments of the fixed glands were frozen and sectioned. Some of the sections were mounted directly on slides in glycerol; others were stained from ten to fifteen minutes with sudan III, and then mounted. Preparations were made in this manner from practically all the adrenal glands studied, warmed to 80 C. (176 F.) in a drying oven, and afterward cooled. As controls for this work, the adrenals from persons meeting sudden death, such as results from gunshot wounds or other severe injuries, were used, and sections prepared in a similar way. The micropolariscopic examination was made soon after, using a very low magnification (28 diameters), and artificial illumination in a dark room to insure uniformity. The adrenals from thirty-four persons dying from delirium tremens were compared with the controls, and in practically every instance the doubly refractive droplets in the delirium tremens adrenals were diminished slightly, moderately, markedly, very markedly, and sometimes in a given area were absent entirely (Table 1).

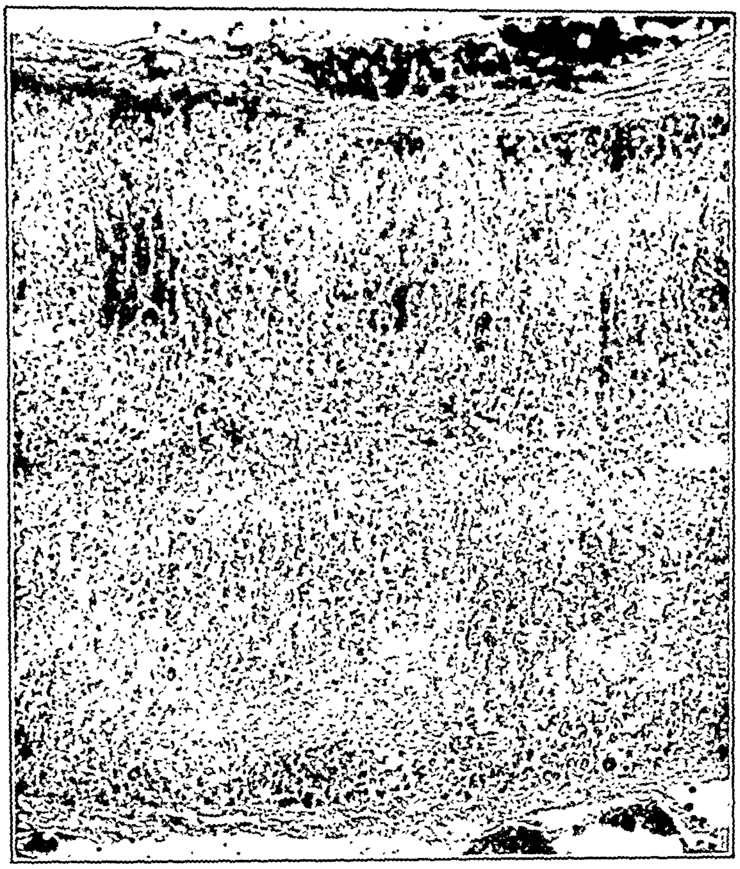

Fig. 3.—Delirium tremens adrenal section stained with sudan III, illustrating the diminution of the lipoids staining with this reagent; Nicol prisms uncrossed; compare with Figure 1; × 38.

Further evidence that the cholesterol content of the adrenals is diminished in delirium tremens was obtained by quantitative chemical estimation. Seven adrenals removed from persons dying with delirium tremens and two controls were analyzed by the following colorimetric method, which, with slight modifications, is the process described by Autenrieth and Funk.[10] While such a colorimetric method may be open to criticism from the point of view of quantitative accuracy, nevertheless, it is probably far better for making comparative estimations of cholesterol than are only rough color determinations such as might be obtained in test-tubes with the Salkowski color reaction.

TABLE 1.—DELIRIUM TREMENS ADRENALS

No.	Double Refractive Lipoids Diminished	Age	Under Observation, Days	Clinical and Necropsy Notes*
1	Moderately	61	14	Small red kidneys; syphilis.
2	Moderately	—	4	An alcoholic for 24 years; marked inflammation of the air passages; *slight sclerosis* of the brain.
3	Moderately	—	19	Was delirious when admitted to the hospital; syphilis; healed empyema; *slight pulmonary* tuberculosis.
4	Moderately	51	—	Tuberculous scars of the thorax; *early bronchopneumonia.*
5	Moderately	—	—	Syphilis; pseudolobar bronchopneumonia.
6	Moderately	33	—	*Delirium tremens clinically* and anatomically.
7	Very markedly	43	—	Delirium tremens complicated by *trauma; extensive* bronchopneumonia.
8	Moderately	35	20	Anatomically only delirium tremens.
9	Very markedly	45	6	Fractured rib; acute pleuritis; syphilis.
10	Moderately	61	—	Chronic nephritis; syphilis; bilateral bronchopneumonia.
11	Very slightly	—	3	Marked pulmonary tuberculosis.
12	Moderately	35	20	Developed lobar pneumonia shortly before death; anatomically lobar pneumonia; chronic nephritis; syphilis.
13	Moderately	35	—	Bilateral bronchopneumonia.
14	Very markedly	35	—	Clinically delirium tremens with early bronchopneumonia.
15	Markedly	35	6	Anatomically delirium tremens and bronchopneumonia.
16	Slightly	37	19	Slight latent pulmonary tuberculosis; marked bronchopneumonia.
17	Moderately	32	13	Chronic alcoholism.
18	Very markedly	38	12	Huge empyema; *chronic nephritis;* syphilis.
19	Very slightly	40	2	Anatomically delirium tremens.
20	Very slightly	38	14	Syphilis.
21	Markedly	38	12	Slight bronchopneumonia; chronic nephritis.
22	Very slightly	47	3	Healing duodenal ulcer; otherwise delirium tremens.
23	Very slightly	39	14	Developed delirium tremens in the hospital.
24	*Moderately*	—	—	Syphilis; chronic nephritis; slight [illegible]nchopneumonia.
25	Very markedly	—	2	M [illegible] syphilis.
26	Slightly	—	3	Ch[illegible] c nephritis; slight bronchopneumonia.
27	Very markedly	—	39	Bronchopneumonia.
28	Moderately	—	7	Chronic alcoholic; bronchopneumonia.
29	Markedly	—	5	Scalp wound; *anatomically* delirium *tremens.*
30	Very markedly	—	2	Anatomically delirium tremens.
31	Very markedly	—	1	Chronic alcoholism; *atrophic* cirrhosis *of* the liver.
32	Very markedly	39	13	Slight bronchopneumonia.
33	Very markedly	45	26	Infected scalp wounds.
34	Moderately	44	4	Anatomically delirium tremens.

NORMAL ADRENALS

The adrenals removed from the bodies of 17 persons meeting sudden death contained an abundance of *doubly refractive* lipoids. Ten of these persons met death as a result of skull fractures; four from gunshot wounds; two from severe trauma, and one from a broken neck.

* I wish to express my appreciation of the kind assistance rendered by Dr. C. E. Sceleth, *physician in charge* at the House of Correction Hospital, Chicago, as well as my gratitude for the suggestions offered by Drs. E. R. Le Count and H. G. Wells.

The fixed adrenals were taken from the 10 per cent. dilution of liquor formaldehydi, the excess fluid blotted off, and

[10] Autenrieth, W., and Funk, Albert: Ueber kolorimetrische Bestimmungsmethoden, München. med. Wchnschr., 1913, lx, 1243.

3 gm. of the ground tissue weighed into a 100-c.c. Erlenmeyer flask. Thirty c.c. of a 25 per cent. potassium hydroxid solution were added, and the tissue saponified on a steam bath for three to four hours. After cooling, the mixture was transferred to a 100-c.c. separatory funnel, extracted once with 30 c.c. of chloroform, and four times with 20 c.c. From 5 to 10 gm. of anhydrous sodium sulphate were added to the combined chloroform extracts to clear the solution, then the mixture was thoroughly shaken, and finally filtered in a dried 100-c.c. graduated, glass-stoppered cylinder through a dry filter, the volume finally being made up by adding chloroform to the filter. One-tenth gm. of cholesterol was dissolved in 50 c.c. of chloroform in a 50-c.c. volumetric flask, a solution used as the known in the determinations about to be mentioned. Five c.c. of the unknown extract were transferred from the stoppered cylinder to a 10-c.c. graduated centrifuge tube by means of a 5-c.c. pipet, 2 c.c. of acetic anhydrid and 0.1 c.c. of concentrated sulphuric acid added, the tube stoppered and shaken. Two c.c. of the known solution were transferred in a pipet to another 10-c.c. graduated centrifuge tube, 3 c.c. of chloroform, 2 c.c. of acetic anhydrid, and 0.1 c.c. of concentrated sulphuric acid added as specified above. Both tubes were then placed in a water bath at from 32 to 35 C. (89.6 to 95 F.) and left there in the dark for fifteen minutes, after which time a flocculent precipitate which usually appeared in the unknown solution was thoroughly sedimented by centrifuging. At this time both tubes contained a fluid having varying intensities of a bright green color, and the solutions were transferred to the chambers of a Duboscq colorimeter for comparison. Control tests were also made using 5 c.c. of chloroform, 2 c.c. of acetic anhydrid, and 0.1 c.c. of concentrated sulphuric acid.

The results of these determinations are given in Table 2.

TABLE 2.—CHOLESTEROL CONTENT OF NORMAL AND DELIRIUM TREMENS ADRENALS BY QUANTITATIVE CHEMICAL ESTIMATION

	Cholesterol per Gram of Moist Adrenal Tissue (Fixed in 10 per cent. Liq. Form. Dil.), Gm.	Condition of the Double Refractive Lipoids
Normal	0.0595	Abundant
	0.1066	Abundant
Average	0.0830	
Delirium tremens	0.0206	Very markedly diminished
	0.0222	Markedly diminished
	0.0166	Very markedly diminished
	0.0113	Very markedly diminished
	0.0233	Markedly diminished
	0.0242	Markedly diminished
	0.0193	Markedly diminished
Average	0.0196	

TABLE 3.—CHOLESTEROL CONTENT OF PATHOLOGIC ADRENALS REPORTED BY CHAUFFARD, LAROCHE AND GREGANT

Pathologic Condition	Number of Adrenals	Cholesterol per 1,000 gm. of Moist Weight Gm.
Renal insufficiency	3	61
		77.45
		40.32
Average		59.59
Chronic nephritis	7	34.64 to 79.68
Average		52.88
Acute infections:		
Typhoid fever	..	6.50
Pneumonia	..	4.70
		20.17
Puerperal sepsis	..	4.10
		4.28
Subacute meningitis	.	1.16
Tetanus	..	1.58
Average		9.58
Tuberculosis	13	2.08 to 31.15
Average		13.50
The low figures corresponding with febrile conditions and severe cachexia range between 2.08 and 5.85 gm., those for the fibroid tuberculosis between 12.8 and 31.15 gm.		
Myeloid leukemia	1	6.50
Asystole	1	17.50
Liver involvement	4	
Nodular carcinoma without jaundice		5.00
Cholelithiasis with icterus		10.20
Biliary calculi with carcinoma of the gall-bladder and icterus		16.80
Carcinoma of the gall-bladder with icterus		15.60
Average		12.35

Chauffard, Laroche and Gregant[11] report the cholesterol content of thirty-six adrenal glands removed from bodies with various pathologic lesions. The method employed in making these determinations is not given. Table 3 contains the results of their study.

Their figures given for the cholesterol content of the adrenals in renal insufficiency and chronic nephritis correspond very closely with those considered normal in this study. Quite probably these disorders exert very little influence on the cholesterol content of the adrenals.

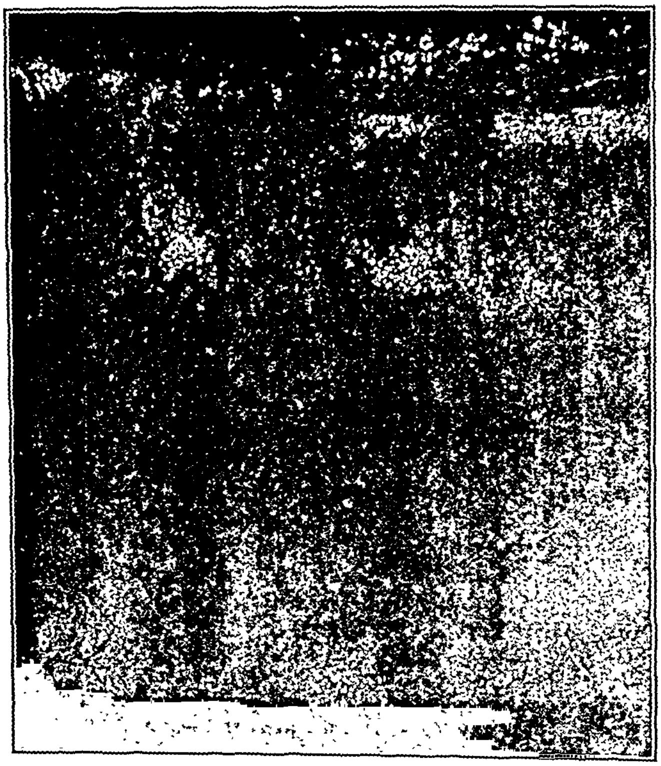

Fig. 4.—Same field illustrated in Figure 3 with the Nicol prisms crossed; observe the striking *diminution* of the double refractive lipoids as well as their irregular distribution; × 38.

The physiologic functions of the adrenals, according to Landau, are not concerned with lipoid formation, but rather the adrenal cortex contains an increased lipoid content under different conditions which have in common only a retention of the lipoids, or are characterized by an abnormally increased lipoid formation, the opposite holding true in conditions accompanied by a lipoid-poor cortex. The variations in the lipoid content are to be considered as secondary to changes in the lipoid content of the body or of the individual organs. With certain limitations, such as inanition and infections, the cholesterol esters behave themselves like the total lipoid content of the adrenals, and probably also are carried to the adrenals and there stored up.

Inasmuch as acute toxic processes in general are associated with a diminution of the double refractive lipoids of the adrenals, the inference lies close that in delirium tremens the body is flooded by some acutely toxic substance, the nature and origin of which is purely hypothetic at present. That something more than the alcohol itself is concerned in producing these changes is derived from the repeated examination of adrenals removed from the bodies of chronic alcoholics without delirium tremens, in which the alterations described were not present.

AUTOGENOUS SERUM IN THE TREATMENT OF PSORIASIS*

HOWARD FOX, M.D.
NEW YORK

The *treatment* of certain obstinate diseases of the skin by human serum is a therapeutic measure of comparatively recent date. In view of some of the favorable reports on this method it seems strange that it has not been given a more extended trial, especially in America. Although the present report is limited to the treatment of one disease, psoriasis, by a single method of serum therapy, it may be of interest to say a few words on the general subject of the use of human serum in treating skin diseases.

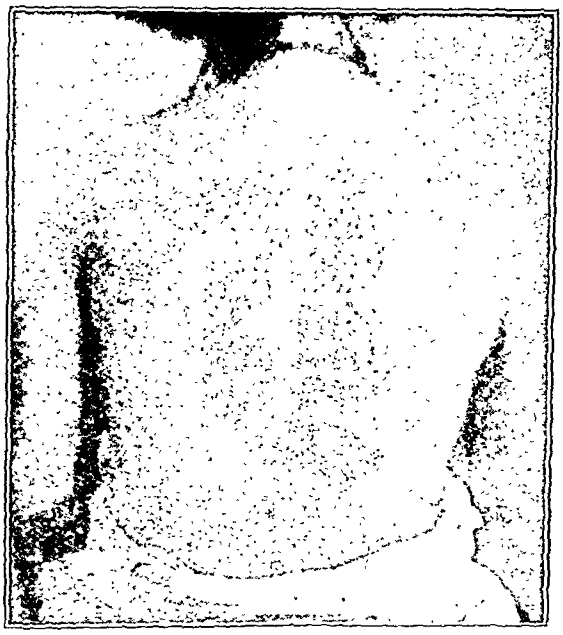

Fig. 1.—Case 5, before treatment; duration, one year.

In December, 1910, a communication was published by Mayer and Linser[1] on the result of treatment of a case of herpes gestationis by injections of serum obtained *from another* pregnant woman. The theoretic basis which led Mayer to suggest this therapeutic trial was as follows: During pregnancy certain poisonous substances are supposed to enter the maternal circulation from the placenta and act as antigens which in the normal case are neutralized by the formation of antibodies. *In certain* cases, however, such antibodies are not produced, the patient suffers from auto-intoxication, as shown clinically by eclampsia, hyperemesis and various distressing forms of skin disease. To supply the supposed lack of antibodies, Mayer suggested that the serum of another healthy gravida should be employed. The patient selected to test this theory was a pregnant woman, aged 24, presenting a severe type of so-called herpes gestationis. She was given 10 c.c. of serum intravenously, obtained from a healthy nonpregnant woman, without showing any improvement. Three days later a second injection from a pregnant woman was given and was followed by an immediate improvement, the eruption disappearing entirely at the end of two weeks. Other good results from this apparently specific treatment of toxic dermatoses of pregnancy were later reported by Mayer,[2] Freund,[3] Linser,[4] Fetzer,[5] Veiel[6] and Rübsamen.[7]

Following his success in treating urticaria of pregnancy, Linser[8] was led to try the serum injections in urticaria and other skin diseases having nothing to do with pregnancy. Good results were reported in twenty-four cases of strophulus and urticaria papulosa of children, in prurigo, pemphigus and hemorrhagic diseases of the skin and mucous membranes.

Heuck[9] later reported good results in urticaria and strophulus of children, and in pruritus senilis. Cases of dermatitis herpetiformis showed decided improvement; slight temporary improvement was noted in cases of neurodermatitis, while the treatment failed to be of value in weeping eczema.

A cure of a case of pemphigus following a single injection of human blood was reported by Praetorius.[10] Six cases of this obstinate disease were treated by von Zumbusch[11] partly by injections of human blood and partly by serum, with no result in some and improvement or cure in others.

The *report* of Ullmann[12] on the serum treatment is less favorable, poor results being obtained in seven cases of dermatitis herpetiformis and no result in eczema of children, though on the other hand, comparatively good results were noted in pruritus.

While all of the foregoing cases were treated with human serum or blood obtained from other individuals (homologous serum) Spiethoff[13] experimented with injections of the patient's own serum (autogenous serum), using this method alone and in combination with homologous and foreign serums. By such combinations of treatment he obtained good results in prurigo, dermatitis herpetiformis, chronic *urticaria, pruritus and psoriasis.* Other allied therapeutic measures that have been tried in the past four years include the treatment of various dermatoses by autogenous blood (Ravaut,[14] Spiethoff[15]), homologous blood (Praetorius), serum from the umbilical cord (Franz[16]) and the serous contents of pemphigus bullae, reinjected in patients with this disease (Holobut and Lenartowicz[17]).

Previous to Spiethoff's publications the result of the serum treatment of psoriasis had not been favorable. Heuck found the treatment of no value in this disease and thought that a beneficial action was not to be expected. In the treatment of psoriasis by autogenous serum, Spiethoff states that in addition to failures he obtained a noteworthy result in two cases. In one case of extensive psoriasis geographica "the patches became pale and flat after the third injection." In another case the involution of the patches began after the first injection of 13 c.c. of inactivated autogenous serum and disappeared after five injections. It was necessary in this case, however, to use local treatment by salves in addition, before a complete disappearance of the eruption was obtained. Spiethoff also mentions a patient with psoriasis applying for treatment for a very severe dermatitis, probably from the use of chrysarobin. Serum treatment was given, after which the dermatitis subsided and the psoriasis disappeared. It may be of interest to add that in the treatment of three cases of psoriasis by autogenous blood, Ravaut failed to see any change in the eruption, although the itching was lessened.

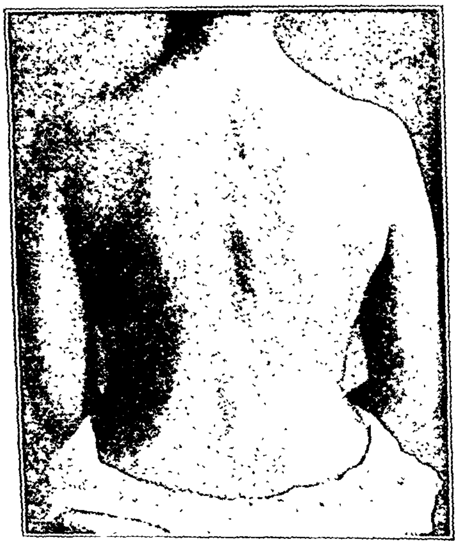

Fig. 2.—Case 5, three weeks after treatment.

Gottheil and Satenstein[18] were the first in this country to experiment with the treatment of skin diseases by human serum, confining their work entirely to the use of active autogenous serum. In their first report on this subject, they stated that "the apparent results from the serum treatments were most noticeable in the psoriasis cases." In a later communication[19] they stated that their results in twelve cases of this disease had been "uniform and extremely satisfactory." In all of these cases the serum treatment was followed by local inunctions of a weak chrysarobin ointment.

My own experience with autogenous serum in psoriasis is derived from the treatment of twenty-eight patients, of whom seventeen were females and eleven males, varying in age from 11 to 54 years. The different forms of the disease such as the guttate, nummular and diffuse were all represented and included varying grades of severity. The duration of the eruption varied in the different cases from 2 to 45 years. All of the patients were treated in an ambulatory manner, with the exception of two, who remained in the hospital for two weeks. The majority belonged to the dispensary class and with few exceptions were fairly faithful in carrying out the treatment.

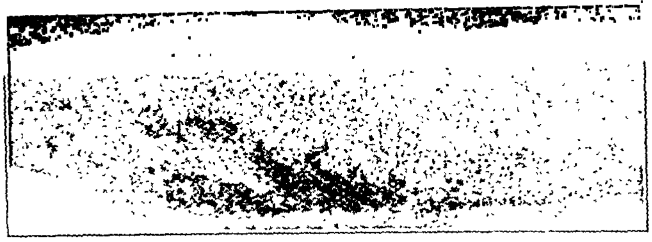

Fig. 3.—Case 10, before treatment.

In all except one case, at least three injections of serum were given, at an average interval of from three to five days. This was immediately followed by the local use of a 10 per cent. chrysarobin ointment, the action of which was increased in certain cases by covering the skin with rubber cloth. No internal medication was given and no particular stress was laid on the diet.

The results of the treatment in general were very satisfactory and in some of the cases decidedly brilliant. The crucial test of the combined serum and local treatment was shown by cases that had been *previously treated by chrysarobin alone.* Some of these patients had been treated by my father, Dr. George Henry Fox, and myself by vigorous inunctions of chrysarobin combined with dietetic methods, and had failed to show practically any response. After the serum injections in combination with the local treatment the results in certain cases were astonishingly good.

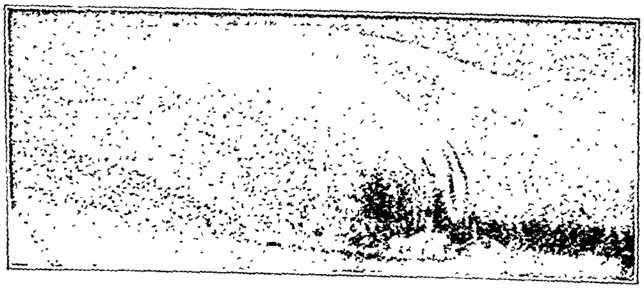

Fig. 4.—Case 10, four weeks after treatment; free of psoriasis for first time in forty-five years.

An idea of the favorable results may be obtained by reading some of the enthusiastic remarks made by the patients themselves. A woman (Case 4), the wife of a physician, had suffered from ten previous attacks of psoriasis and was thoroughly familiar with all of the usual methods of treatment. She was delighted at the rapidity with which her eruption disappeared, which she characterized as being "perfectly marvelous." Another patient (Case 10) thought the result was "like magic" and added that he had tried "all kinds of medicines and doctors in Europe and America for forty years without any result." Another woman (Case 12) said she "never saw chrysarobin take hold so rapidly and never saw the eruption fade so fast as from the present treatment." The daughter of the patient (Case 13) also stated that "although this was by all odds the worst attack she had ever had, the eruption had never disappeared so quickly." Another patient (Case 16) who had suffered from psoriasis for thirty years said that he could not remember when the disease had been so well under control. In his case it should be added that chrysarobin had been previously used on and off for a period of four years. One of my patients (Case 11) had been previously treated for two months with chrysarobin ointment, covered a good deal of the time by an impermeable suit of rubber cloth. In spite of this vigorous treatment the result had been most discouraging. After he had received three injections of autogenous serum, however, and had then been treated by chrysarobin, a lively dermatitis was caused and the greater part of the eruption promptly disappeared. Three other cases that we had previously treated seemed to be immune to any local action of chrysarobin, as it was apparently impossible to produce the slightest dermatitis from a 10 per cent. or 20 per cent. ointment. In one of these cases (Case 5) the result of the new treatment was certainly brilliant, while in two others (Cases 1 and 2) it was gratifying to the patients even though a certain amount of the eruption still remained. One of my patients (Case 28) who seemed most pleased with the treatment was a man who was relieved of his psoriasis for the first time in twenty-four years. He had been vigorously treated on former occasions by chrysarobin alone, but had never seen such a rapid effect from its use as at present when the combined method of treatment was employed.

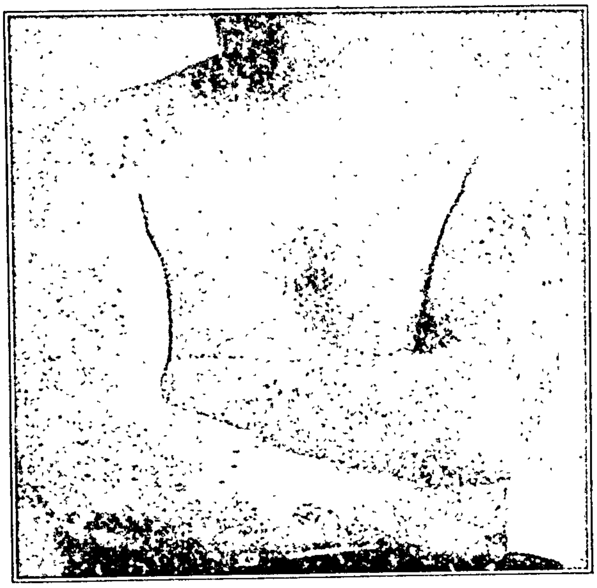

Fig. 5.—Case 11, before treatment; duration, three years.

It might be thought that the good results were not due to the serum injections but simply to the chrysarobin, as the latter drug was used in every case. To prove that the serum injections in some cases at least were responsible for the improvement it is only necessary to repeat that these cases had previously been treated with little or no result with chrysarobin and it was only when the inunctions of this remedy were combined with serum injections that the favorable results were obtained.

From the injections alone I was unable to see any decided effect on the lesions except in one case which might have been a coincidence. An improvement after injections alone was, however, noted by Gottheil and Satenstein, while as above stated in a case of Spiethoff's the attack of psoriasis was entirely relieved by the sole use of the injections.

No ill effects from the serum treatment were observed except in one case (Case 4) in which the third injection was followed by a rather violent urticaria lasting a week. Urticarial rashes were also observed by Linser in several cases, generally lasting from twelve to twenty-four hours. In the case of autogenous serum injections, it is hardly conceivable that any serious ill effects could result when proper aseptic precautions were observed. This cannot be said of the use of a foreign serum in which the possibility of anaphylaxis is always present. In the case of injections of homologous serum the possible transmission of syphilis or tuberculosis must be considered. For this reason the autogenous serum has an advantage over homologous serum and it has the further advantage of greater simplicity, as the patient who receives the injection is also the donor of the blood.

The technic of the injections is perfectly simple for those who have had experience in making venipunctures or giving intravenous injections. For those who have not had this practice it cannot be called difficult. My own plan has consisted at each sitting in drawing 50 c.c. of blood from the cubital vein, by means of a MacRae needle, into a sterile cylindrical glass bottle. The bottle and its contents were then properly balanced and placed in an electric centrifuge having a speed of eighteen hundred or more revolutions a minute. When the serum was thoroughly separated from the corpuscles and fibrin it was drawn off into a glass syringe and injected without delay, either intravenously or intramuscularly. The amount of serum that was generally obtained from the 50 c.c. of blood varied between 15 and 25 c.c., the latter being the maximum. In every case the serum was injected in an active state. As a rule the entire procedure of drawing the blood and

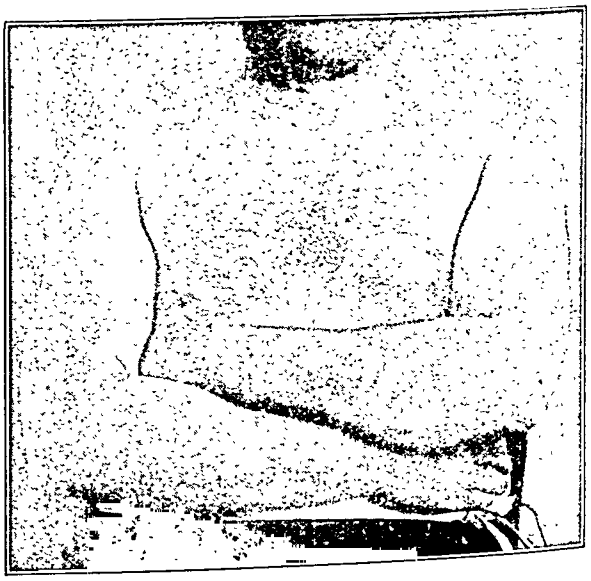

Fig. 6.—Case 11, three weeks after treatment.

injecting the serum was completed in half an hour or less.

The question as to why injections of human serum should have a curative action in certain dermatoses is certainly a difficult one to answer. That such an effect is not simply due to the power of suggestion was shown by Linser[20] in control cases in which salt solution was injected in place of the serum. The same writer also suggested that the action of the serum might be due to the addition of complement to the blood of a patient in which this substance was deficient. Ullmann, however, by titration, failed to find any deficiency of complement in his patients who responded well to treatment. Furthermore, it was found that good results were obtained by the use of serum that had been entirely deprived of complement (inactivated). That this suggestion of an addition of complement does not apply to patients treated with their own serum is, of course, self evident.

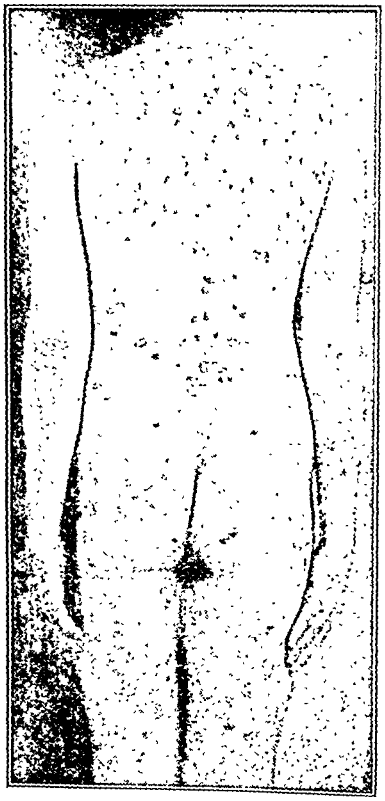

Fig. 7.—Case 28, before treatment.

It was also suggested by Linser that the beneficial results might have a connection with the eosinophil cells. He found that with the lessening of the intensity of the eruption there was a lessening of the number of eosinophil cells, while Ullmann, on the other hand, failed to find a regular decrease in their number after serum treatment but "rather in certain cases an increase." As we know so little of the real significance of the eosinophils, it seems idle to speculate at present on their causative relation to the serum treatment of skin diseases.

The idea naturally presents itself that the beneficial action of autogenous serum injections might be solely due to the bloodletting. That this therapeutic measure may lessen the intensity of some inflammatory skin diseases there can be no doubt; that the results obtained were due, however, to the injections of serum and not merely to the venipuncture has been shown by comparative tests with the two methods of treatment.

The results of treatment of the toxic dermatoses by serum of other healthy pregnant women were thought at first to be due to a specific reaction of the serum. That this was not the case seems apparent from the fact that similar results in toxic dermatoses of pregnancy were obtained by Freund[21] with horse serum, by Hofbauer[22] with pituitary extract and by Rissmann[23] and Eichmann[24] with Ringer's fluid (solution of sodium, calcium and potassium chlorid and ammonium carbonate).

In speaking of his case of pemphigus malignus cured by a single injection of human blood, Praetorius suggested that the curative substances were perhaps protective ferments in the sense of Abderhalden, whose duty it was to prevent the further formation of harmful intermediary products of metabolism or perhaps to destroy injurious secretions of the ductless glands.

Finally, Luitlen[25] showed by animal experimentation that inflammatory reactions of the skin to external irritants could be favorably influenced by injections of homologous, autogenous or foreign serum or homologous blood. Further experiments showed that parenteral introduction of colloidal substances, even when not protein in nature, as colloidal silicic acid and soluble starch, could also influence the inflammatory condition of the skin. He concluded that the action of the serum in the treatment of skin diseases had nothing to do with its antigenic function, but that the introduction into the system of a colloidal complex brought about changes of a character as yet unknown. Spiethoff,[26] whose investigations had been entirely clinical, agreed with the conclusions of Luitlen.

From the foregoing it is evident that we are not in a position to give an entirely definite explanation of the action of human serum in the treatment of psoriasis. I can merely say that in some unknown way the serum injections seem to have caused changes which make it possible for the chrysarobin inunctions to bring about better results than they could otherwise have attained.

The results of treatment recorded in this paper (see

accompanying table) refer to the effect of the combined serum and chrysarobin method on individual attacks of psoriasis. For this purpose it seems to me that the new method is of real value. As to its possible effect in preventing recurrences of the disease, the time is too short for conclusions to be drawn. To hope for such a result would be too much to expect in a disease so peculiarly prone to recurrence. Even if future attacks cannot be prevented, in the present state of our knowledge, it is at least a satisfaction to have an improvement in the method of treating the individual attacks of such an obstinate and chronic disease as psoriasis.

CONCLUSIONS

As a result of my own observations in a limited number of cases I would draw the following conclusions:

1. Autogenous serum, when used alone, does not appear to be of value in the treatment of psoriasis.
2. It is of decided value in many cases when used in conjunction with chrysarobin. Obstinate cases of psoriasis that have long resisted vigorous treatment with chrysarobin ointment will often yield to this remedy when injections of autogenous serum are given.
3. Intravenous injections of autogenous serum, if properly given, are entirely devoid of danger.
4. The technic of preparing the serum and giving the injections is comparatively simple.

I wish to express my thanks to Drs. Edward Pisko and Benjamin F. Ochs for their kindness in supplying some of the material.

[Note.—Since this article was submitted for publication a communication has appeared in the *Journal of Cutaneous Diseases* (1914, xxxii, 780) by Hilario entitled "A Contribution to the Autoserotherapy of Certain Diseases of the Skin." Hilario reports excellent results in the treatment of five cases of psoriasis by the combined method of injections of autogenous serum and inunctions of a weak (2 per cent.) chrysarobin ointment. A comparatively large number of injections was given (as high as ten in one case) the amount of serum varying from 15 to 40 c.c. Hilario concludes that "The autoserum plays a very active influence in the treatment of psoriasis in the way of reducing the resistance of the psoriatic tissue, thereby rendering it more apt to be acted on by the chrysarobin, in weak percentages."]

Scientific and Literary Imagination.—The imagination of Darwin, of Pasteur, for example, is as high and productive a form of imagination as that of Dante, or Goethe or even Shakespeare, if we regard the human uses which result from the exercise of imaginative powers: and mean by human uses not merely meat and drink, clothes and shelter, but also the satisfaction of mental and spiritual needs.—Charles W. Eliot.

OBSERVATIONS ON MILITARY SURGERY IN THE EARLY WEEKS OF THE WAR

J. P. HOGUET, M.D.
Adjunct Attending Surgeon to Bellevue Hospital; Assistant Attending Surgeon to the General Memorial Hospital and Hospital for the Relief of the Ruptured and Crippled
NEW YORK

It has been said by a number of capable military surgeons within the last decade that the treatment of modern gunshot wounds would be a much simpler proposition now than in former years. It was shown that in the Spanish-American and the Russo-Japanese wars the effect of the modern high-speed pointed rifle bullet was a humane one. The wounds were small, non-lacerated, and above all, clean, with comparatively few exceptions.

This might have been true formerly, when the number of men engaged was comparatively few, when transportation was rapid and when there was little use of the modern high-powered shrapnel shells, but from personal observation of the wounded in France during the early weeks of the war I can state without reservation that this is not the case.

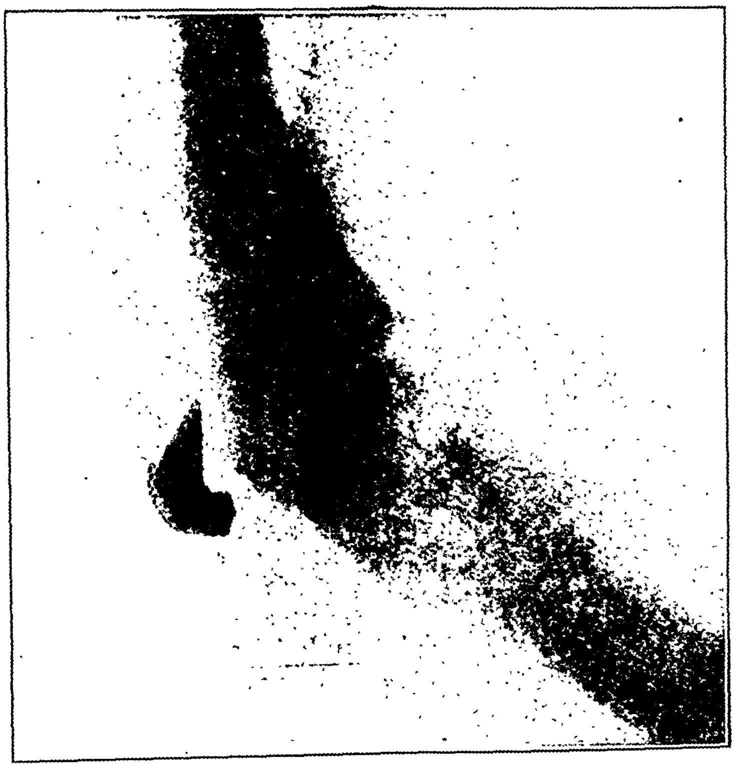

Fig. 1.—Ricochet or deformed bullet. This bullet had gone through the skin of the side of the thorax and then lodged in the elbow between the skin and the olecranon. The bullet had enough force left to fracture the humerus but not to shatter it.

Many surgeons have made the observation that in the month of August a large number of those injured by rifle bullets had absolutely clean wounds, especially when there was no involvement of bony structures. Since then the daily life of the soldier in the field has been an extremely arduous one. Facilities for personal cleanliness have been practically nil, and the average soldier's clothing in the field is in a frightfully dirty condition. This is well illustrated by the remark of one of the wounded who was being undressed on his arrival at a base hospital in Paris in November: he said that the trousers that were then being removed were the ones he started to the front in in the early days of August, and that he had not had them off once since then. The hospital bed was the first one he had been in since he had been called from his own home by the mobilization. It is hard to conceive how a bullet traversing such clothes as these can stay aseptic.

Shrapnel wounds — those caused by the lead shrapnel balls or parts of the casing of the shell — are, of course, attended by a greater amount of infection; on account of the greater size of the ball or shell fragment and their slower velocity, more clothes or other infectious material are brought into a wound, which is very much bruised and lacerated. Probably all these infections occur at the time that the man is wounded. Of course, there are a great number of wounded who cannot be immediately removed from the firing line and who lie for hours exposed to the rifle and shell fire of both their own men and the enemy, but luckily these are the exception. Most of the wounded are first dressed at the front by the field surgeons, the great majority of whom do their work with judgment and ability notwithstanding the surroundings, with little equipment and amid danger.

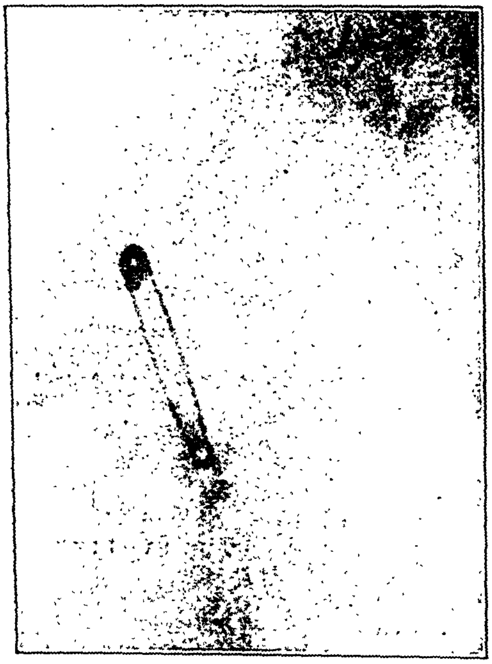

Fig. 2.—Typical butterfly fracture from bullet traveling at high speed.

Transportation of the wounded, considering all the difficulties and the great number to be transported, is being creditably done in France. The more seriously injured are being taken care of in the so-called "flying" ambulances which always stay within a few miles of the firing line. Those less seriously injured are removed to the trains, which now are fairly well equipped with the necessary supplies, and well heated and lighted. In charge of each train is an army surgeon, sometimes with assistants, and practically always with orderlies who attend to the comfort and minor wants of the men. Dressings are done *en route,* and these are practically always in good condition on the patient's arrival at the base hospital.

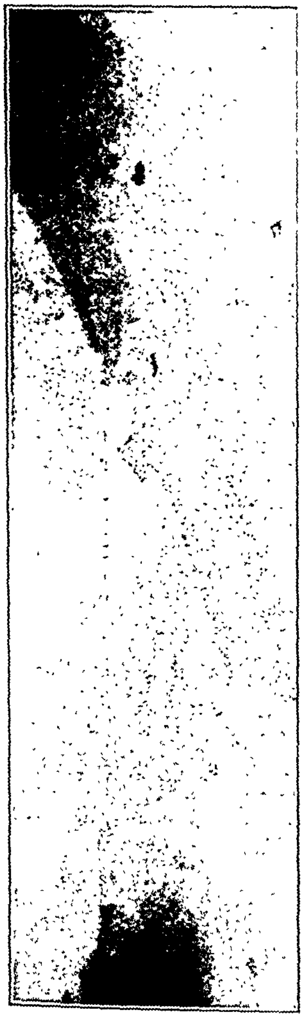

Fig. 3.—Fracture of humerus from shrapnel.

The military authorities up to the present have shown a desire to send as many wounded as possible to the south of France, and to keep the hospitals in the North empty, but at practically all the more important cities along the railroad there are temporary hospitals at the station into which those who are too sick to stand further traveling are taken, and then transferred to a permanent hospital in that city. At almost all stations on the railroads leading from the war zone kitchens have been established by the Red Cross, and the "secours aux blessés militaires," where hot food is supplied to the wounded.

Then, too, from the Pas de Calais district, where the fighting of late has been so heavy, a great number of wounded can be evacuated by the hospital ships to such ports as Cherbourg and Havre, further south, or directly to England. These ships are well equipped, are large and comfortable, and each has a complete staff of surgeons who do whatever emergency operating there is to be done on board. All the patients are dressed as often as necessary, and on some of the ships there is a Roentgen-ray plant where every wounded man is roentgenographed, the plate developed and sent with him to the base hospital when he disembarks.

Practically all the wounds seen are from rifle bullets and shrapnel. One saber wound was observed at the American Ambulance at Neuilly[1] since the beginning of the war; there were no bayonet wounds. Accidental injuries, such as simple fractures of the leg or foot from being thrown from a horse, were sometimes seen, but were very rare.

RIFLE BULLET WOUNDS

The wound of entrance of the pointed .30 caliber cupronickeled steel rifle bullet now used by the Germans is generally a small one—smaller than the diameter of the bullet—while that of exit is generally larger. The course of the bullet is generally straight, but of course one that is nearly spent may be deflected or even stopped by a strong bone such as the femur. Large lacerated wounds are sometimes made by the so-called "ricochet" bullet (Fig. 1), that is, one that has struck a hard substance and has been deformed by bursting its jacket and then rebounding, striking the person. These are the wounds that give rise to the report that the enemy is using dumdum or explosive bullets. In order to prove the use of such it would be necessary to actually remove such a bullet from a wound.

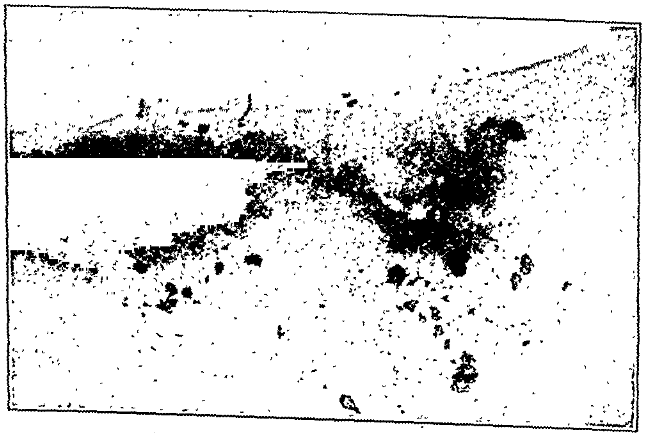

Fig. 4.—Shrapnel wounds of the foot.

The effect of the regulation German rifle bullet on each part will later be taken up, but its effect on bone must be discussed here. When a strong bone, such as the humerus or femur, is struck by a bullet within its zone of maximum speed (5,465 yards); one of two things may happen: Either the bone is cleanly perforated — and this is very rare — or else it is completely shattered. In the latter case we have the typical butterfly fracture, as is shown in Figure 2. In these cases there is such a transmission of energy from the bullet traveling at high speed that extensive comminution results. Near the center of the fracture the fragments are apt to be small, but long fissures extend up and down the shaft of the bone—in some cases into the epiphyses. These fissures make some of the fragments of a large size. On the other hand, when a bullet at the end of its trajectory strikes a bone, a simple fracture results, which very much resembles those caused by indirect violence in occupational injuries. In one instance the bullet, after striking the bone, had its force so nearly expended that it remained in the limb. Short flat bones, such as the clavicle or ribs, are generally shattered, especially when the blow is a glancing one. Small bones like the tarsus or carpus are most often extensively comminuted.

---

[1] "Ambulance" is the name given to the military hospital; Neuilly is a suburb of Paris.

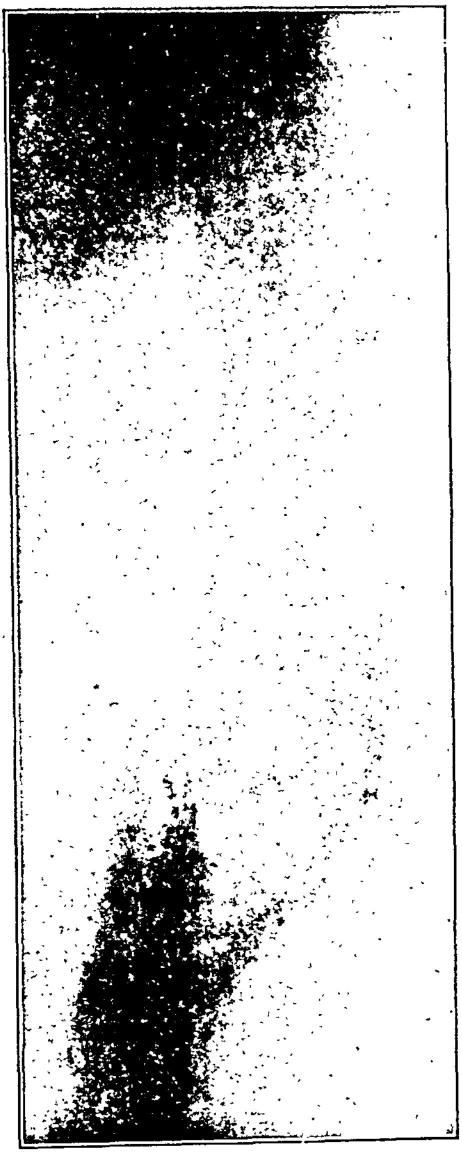

Fig. 5. — Fracture of femur from shrapnel.

SHRAPNEL WOUNDS

Wounds from shrapnel are, in general, more severe than those from rifle bullets. A shrapnel wound is one made by a shrapnel ball, or part of the casing of the shell. The former is a solid lead ball of about .50 caliber, forty balls to the pound. When the shell explodes these balls are scattered in all directions in the so-called cone of dispersion, but not at a very great velocity. The shell itself is shattered into innumerable pieces of varying sizes. Hence it can be readily seen that shell wounds result from large missles traveling at a comparatively low rate of speed, and are therefore characterized by a large amount of laceration to the parts. Perforating shrapnel wounds are rarely seen, in most cases the missiles lodging in the tissues and forcing in with them a large amount of clothing or parts of the soldier's equipment. These wounds, of course, vary greatly in size and are practically always multiple — seventy-five having been counted in one soldier. The destructive effect of shrapnel on bones is very great. Here the butterfly fracture is hardly ever seen, except when the bone is struck by one piece. In most cases there is an extensive comminution amounting really to a grinding of fragments, being extremely small, about the size of pebbles (Figs. 3, 4 and 5).

VARIOUS INJURIES

The exact statistics as to the relative frequency of injuries to various parts will not be brought out till after the close of the war, but it might be well to describe briefly here the more characteristic injuries of each part.

One saber cut of the scalp, which was a simple wound without fracture of the skull, was noted. One case in which a rifle bullet had completely traversed the skull from side to side was seen at the Beaujon Hospital on the service of Dr. Tuffier, and was the only one of its kind observed. Cases of furrow wounds of the skull were not uncommon; in most of these the furrow was anteroposterior and generally on the side of the head; they were most often accompanied by an extensive fracture of both inner and outer tables, but very little comminution was present. In one case of this class in which I operated at the American Ambulance, there was an extensive right-side extradural and subdural clot. There was a complete motor paralysis of the opposite arm and leg, which cleared up two weeks after the removal of the clot. Compound fractures of all parts of the skull were very frequent from shrapnel wounds, in which a portion of the overlying tissues had been torn away. Many cases were seen in which a portion of the soft parts of the forehead, together with an eye, had been completely destroyed by shrapnel. Here there was generally a fracture of the frontal bone through which brain tissue exuded. In one patient, received after he had been in a hospital at Arras for a week subsequent to being wounded, I discovered at operation an abscess

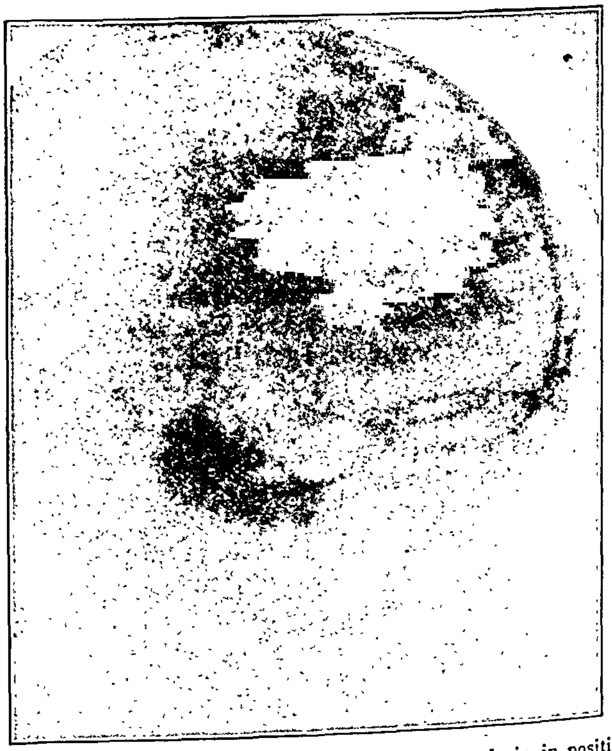

Fig. 6.—Abscess of frontal lobe of the brain with drain in position.

in the frontal lobe on the right side. There were also some small particles of shrapnel behind the right eye (Fig. 6).

Wounds of the face and eyes by rifle bullets were not uncommon, especially since a great deal of the fighting has been done in trenches. Two cases in which the bullet had entered one cheek, completely traversing the head and coming out at the opposite mastoid process, were seen. Both of these were uncomplicated, except for a complete facial paralysis on the side of the wound of exit. Several cases of the destruction of one or both eyes from bullets coming from the side were also observed. Shrapnel wounds of the face were one of the commonest of injuries. Some of the patients simply had very small particles of shell-casing embedded in the skin. Many others had large portions of the face destroyed, and of these there were numerous cases of injuries to the eyes and nose.

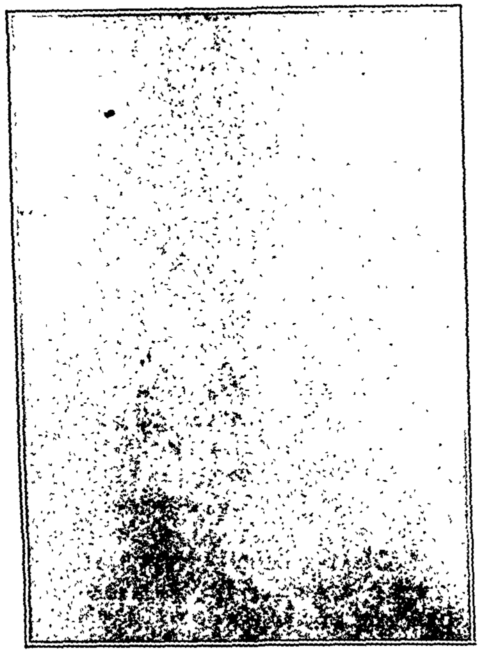

Fig. 7.—Shrapnel ball in pericardial sac. The picture is not very distinct as the ball was moved by every heart beat.

Fractures of the inferior maxilla by both bullets and shrapnel were numerous. They were all very complicated cases, as they were compound either externally or toward the mouth, or both, and the fractures were practically always multiple. In the shrapnel injuries part of the chin or side of the face was often torn away, and in many cases some of the underlying bone was gone. In most of the Paris hospitals these cases were turned over to the dental surgeons, whose work was excellent, and whose results were often brilliant. A number of very complicated fractures with loss of bone and overlying tissues were seen at the Beaujon hospital. Here the plan of treatment was to apply an interdental wire splint immediately on the patient's entrance. The wound of the soft parts was dressed until infection ceased, and any operation in the way of removal of dead bone, or plastic work, was done only when the wound was perfectly clean. This method apparently gave better results than when the interdental splint was applied only when the wound was clean.

Wounds in the neck are comparatively rarely seen. One artillery-man was seen with a large lacerated wound in the middle of the neck from a piece of shell. When taken off the field this patient seemed to be breathing his last. As the piece of the shrapnel was visible through the external wound, it was removed by the field surgeon. The patient immediately began to breathe normally, and it was then discovered that the phrenic nerve had been pressed on. In this case there was surprisingly little loss of blood. Another patient admitted to the American Ambulance with a bullet wound in the neck was almost exsanguinated, and it was found on necropsy that the vertebral artery had been completely severed. Large hematomas of the neck were sometimes seen, and it was found best in all these patients to cut down and ligate the injured vessels immediately. One or two isolated cases of injury to the cervical and brachial plexuses were noted, but were very rare.

Wounds of the chest were not common. Penetrating rifle wounds were sometimes seen. In some the bullet had completely traversed the thorax, and in a few it had remained in it. In all of these cases there was usually an extensive hemothorax, which practically always disappeared slowly of itself, or after a few aspirations. Only one case of empyema was observed, and in this case there was a perforation of the chest wall by a piece of shrapnel 1 by 2 inches in size. Practically all the chest cases showed a complicating fracture of one or more ribs with a considerable amount of comminution. A few had signs of pulmonary consolidation, which lasted a short while and cleared up.

Two very interesting heart cases were seen. In one a shrapnel ball had entered the left lumbar region, completely traversing the left side of the abdomen, and was found by roentgenoscopic examination lying free within the pericardial sac. The ball moved freely up and down at every movement of the heart and apparently caused the patient no inconvenience (Fig. 7). The other case of this kind was seen at necropsy

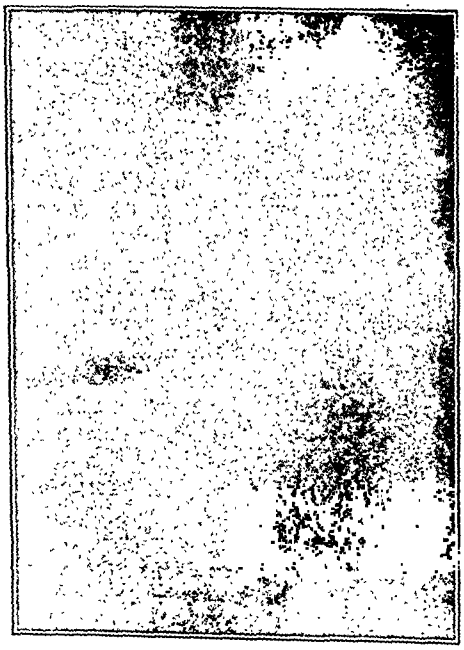

Fig. 8.—Bullet from a machine gun lodged in the abdominal wall, between the peritoneum and the internal oblique muscle.

in a patient who lived only a few days after entering the hospital. Here a large piece of shrapnel had completely traversed the abdomen and lodged in the heart muscle.

A surprisingly large number of patients had nonpenetrating wounds of the abdominal wall. Many of these simply had very small particles of shrapnel embedded under the skin. In some the fragments of shrapnel were quite large, the largest being 1¾ by 2½ inches in size. Several cases in which bullets had entered the side of the abdomen and had pursued their course under the skin were noted. In one instance the bullet of a rapid-fire gun entered the right upper abdomen over the eighth rib in front. On operation, I found it in the left iliac region between the peritoneum and the internal oblique muscle (Fig. 8).

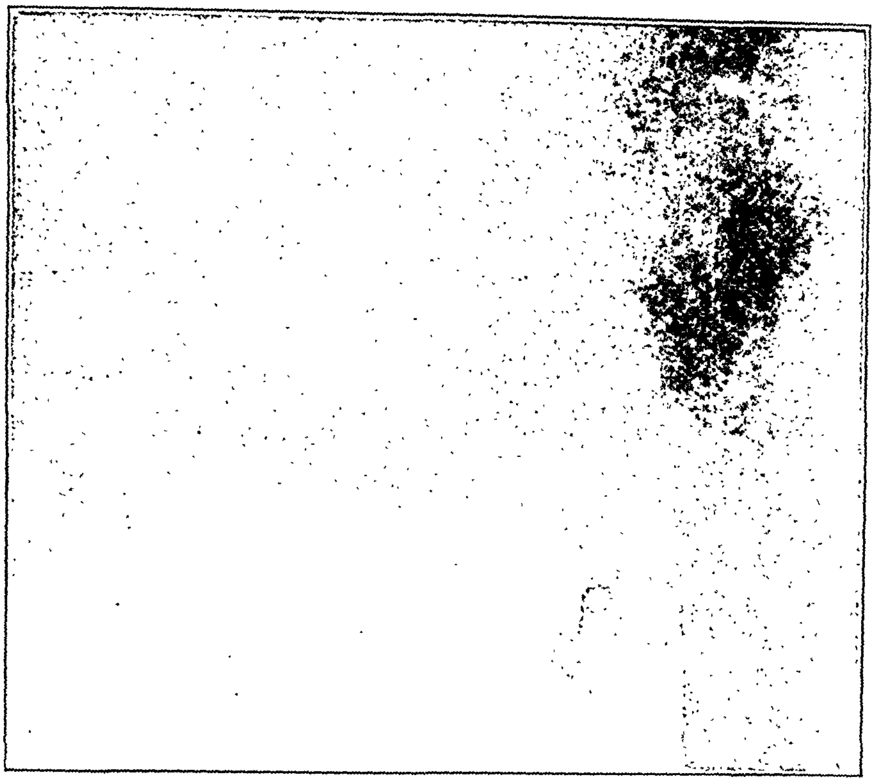

Fig. 9.—Shrapnel in perineum.

That the modern rifle bullet is not a harmless one when it penetrates the abdomen now seems to be an indubitable fact. The typical penetrating wounds are not seen at the base hospitals, or if they are they are seen only in the stage in which a localized abscess has been formed. From accounts of a number of men who have been doing active service at the front, few laparotomies are done there on account of inadequate facilities. The opinion of most of these men is that there is little effort on the part of the mucous membrane to close up the perforation. Most patients with abdominal wounds are now being transported to the nearest base hospital in a sitting position, and there treated expectantly. Luckily localized abscess formation is the rule, and in no case of this kind is operation performed at the base hospital unless there is a definite abscess. One case was seen at the American Ambulance in which the bullet had entered the left iliac region and had made its exit through the middle of the sacrum. This patient had no abdominal symptoms for almost one month, when an abscess began to develop on the left side. A number of cases of fecal fistulas were seen which had been evacuated to the base hospitals from those at the front after the acute symptoms had subsided. The majority were low down in the iliac, or lumbar regions, but several unusual ones were seen higher up in the abdomen, the highest being in the sixth intercostal space in the anterior axillary line.

Bullet wounds in the lower part of the abdomen anteriorly or through the buttocks posteriorly have been found to be especially interesting, and particularly fatal. The reason for this is that here there is often a perforation of the large intestine with a resulting abscess. Apparently a retroperitoneal cellulitis is set up in the neighborhood, so that a large blood-vessel may be eroded and a fatal hemorrhage ensue.

Wounds of the perineum are comparatively rare, though several cases were seen in which shrapnel balls or shell fragments were found lodged there (Fig. 9). The greatest amount of destruction of tissue from shrapnel observed was seen in a case of this kind. Practically all of the perineum had been destroyed here and a large part of the tissues on the inner aspect of both thighs.

By far the most frequent and most interesting cases from a surgical point of view that the war has brought out so far are those of injuries to the extremities. Here again the very superficial injuries from rifle bullets, and shrapnel must be emphasized. Some of the very superficial injuries from rifle bullets, or some of the more superficial wounds *en séton* may sometimes remain clean, but practically every other wound of an extremity from either bullet or shrapnel is infected at this stage of the war. It is for this reason that the compound fractures of the humerus and femur are so very serious, and the latter much more so than the former. When a fracture occurs in either of these bones very long fissures are most often present. There is infection of the soft parts and bone from the very beginning. In the former the infection seems to travel along the fascial planes between the muscles, so that abscesses may subsequently be found at a considerable distance both from the fracture and the wound of entrance. In the bone an acute osteomyelitis starts in at the main point of fracture and slowly spreads along each of the fissures. Hence we see the small fragments extruded first and later the large ones.

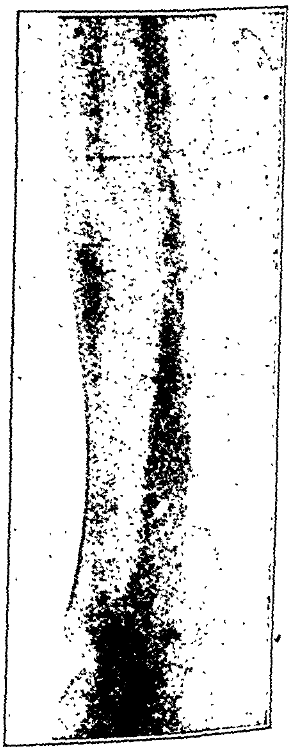

Fig. 10.—Metal shoe-lace clasp driven into the leg by a shell explosion.

Several instances have been noted in which the fissures have extended into the epiphyses, and on account of this osteomyelitis we find an infected joint in a rather short period of time. Where the diaphysis of a long bone is struck there is extensive comminution, but fissuring into the shaft rarely occurs. In these cases, of course, infection of the joint is immediate. Compound infected fractures of the humerus, even when accompanied by an extensive loss of bone and soft parts, yield much more readily to treatment than do similar injuries to the femur. Whether this is due to a better blood-supply to the upper extremity, or whether the foyer of fracture is easier of access here will not now be discussed, but the fact remains, and will probably become more and more evident during the course of the war. Amputation of the arm has rarely to be resorted to unless there is injury to the brachial artery high up, or unless some complication, such as gas gangrene, sets in. Amputation through the thigh, however, must be done in a fairly large proportion of cases, as it must be borne in mind that these patients become rapidly septic so that the first indication is to save the patient's life, the second to save the limb and the third to preserve as much function as possible. Conservatism in the treatment of these fractures is the rule in France and England. I have it on very good authority that such is not the case in the German army.

Conservatism is, of course, to be encouraged, but the treatment of these fractures is one that requires absolutely the best of surgical judgment. Good and efficient drainage must be established early and be maintained. Loose fragments of bone or pieces of shrapnel must be removed. The postoperative treatment is more important than the operation. The limb must be immobilized, and in the case of the femur, extension must be employed. A plaster hip spica, although carrying out both immobilization and extension, has been found to be impracticable. It soon becomes loose as the swelling of the limb decreases, and is dirtied in a very short time, as the amount of discharge from these wounds is enormous. The simplest method and the most practicable consists in extension with weights and immobilization by means of wooden splints on a fracture pillow. An idea of the gravity of these fractures, and the difficulties in their treatment, may be somewhat appreciated when it is remembered that these patients have for several months been living under a terrible strain, and often with insufficient food. The reason that conservatism can be used at all is that all these patients are young men.

Of the two dreaded complications of gunshot injuries — tetanus and gas gangrene — it is much too early in the war to speak. The French government had a supply of antitetanic serum on hand, so that it was a rule in many base hospitals that every soldier should be given an immunizing dose on admission. An idea of the comparative rarity of tetanus can be gathered when it is stated that in four hospitals in Paris — each with a capacity of about 400 beds — not one has had more than six cases.

Gas gangrene, however, is much more common and is especially prone to follow shrapnel wounds of the thigh. The methods of treatment differ in various hospitals. Most of the French surgeons do not believe in extremely large incisions for drainage, but make comparatively small ones, which are frequently irrigated with peroxid. Many are in favor of draining and forcing oxygen gas under pressure into the affected tissues for a considerable length of time — from twelve to seventy hours. This can be repeated at intervals if the process does not resolve. Both these methods of treatment have given good results in some cases, but in many others amputation has to be done, and very often this is of little avail.

For the privilege of having been able to operate in and treat a number of the cases mentioned here I wish to thank Dr. Du Bouchet, Surgeon-in-Chief of the American Ambulance at Neuilly. To the many other surgeons in Paris, by whose courtesy I was able to see the cases under their care, my thanks are also due. The roentgenograms reproduced here were kindly made for me by Dr. Jaugeas and Mr. King of the roentgenographic department of the American Ambulance at Neuilly.

THE RELATION OF POSTURE AND INTESTINAL DERANGEMENTS TO COXITIS*

ROBERT B. OSGOOD, M.D.
BOSTON

The title of this communication is misleading. One has a right to infer that I shall at least attempt to explain the relation of posture and intestinal derangements to coxitis. I shall offer no explanation, however, and there should be an interrogation mark after the last word.

The paper is simply a report and a consideration of three cases in which there was an apparent relationship between faulty posture or intestinal derangements and coxitis, and in which the discovery of this relation made unnecessary any prolonged local treatment of the coxitis. The excuse for its presentation is the hope that not all of those present have noted such an association. If this is so and your experience should tally with mine it is possible that you may occasionally be spared a modicum of anxiety, a few families may be spared the distress which the diagnosis of tuberculosis always brings, and certain patients may be spared a prolonged and irksome treatment which may not be demanded.

You are all familiar with the belief held by Sir Arbuthnot Lane[1] that unless the capacity of the several tissues of the body to resist the entry of certain organisms is inhibited by an auto-intoxication resulting from intestinal stasis, it is impossible for these diseases to develop. Therefore, to meet these diseases he adopts measures to improve the drainage scheme and cites cases in which rapid disappearance of large masses of tuberculous glands in the abdomen has occurred, following disconnection of the large bowel.

Fraser,[2] writing on the types of organism in bone and joint tuberculosis in children, is quite convinced that the more common bovine form enters usually by the mouth in milk. It is probably true that an intestinal stasis favors extension to the bones and joints.

Barrington-Ward,[3] working at Great Ormond Street, reports a case of double tuberculous disease of the hip with sinuses, in which orthopedic treatment had been unavailing, but in which rapid recovery followed a short circuiting operation after the manner of Mr. Lane.

It is not, however, to suggest that faulty posture and intestinal derangements bear a causative relation to tuberculous coxitis that these cases are reported. I should be disinclined to deny the possibility of such a relationship, but in this paper I wish rather to suggest that associated with certain intestinal derangements and faulty posture in children there may exist a toxemic arthritis indistinguishable clinically from tuberculosis of the hip.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[1] Lane, Arbuthnot: Lancet, London, Dec. 14, 1912.

[2] Fraser, S.: Brit. Med. Jour., April 12, 1913.

[3] Barrington-Ward, L. E.: Surg., Gynec. and Obst., July, 1912.

Thanks to the work of careful pathologists, among whom your Chairman and honored guest are eminent, we know many of the changes which take place in tuberculous disease of the joints. These changes are fairly constant. Tubercles are present, the synovial membrane proliferates, erosion of cartilage appears, and bone foci follow or antedate the involvement of the synovia.

Poncet[4] and others have described a *rhumatisme tuberculeuse* due to toxins elaborated in, and disseminated from, a tuberculous focus in some other part of the body. If such a condition obtains it is probable that joints thus affected may completely recover if the focus can be eradicated.

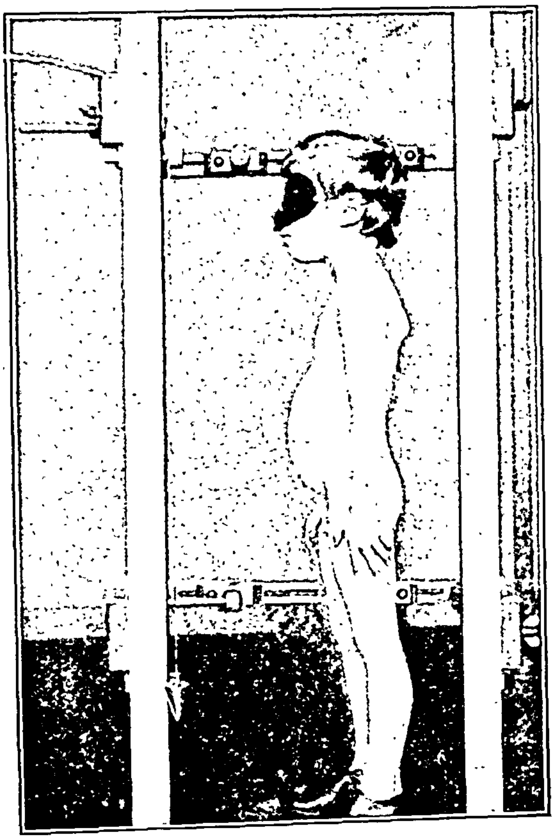

Fig. 1.—Natural standing position, Case 2.

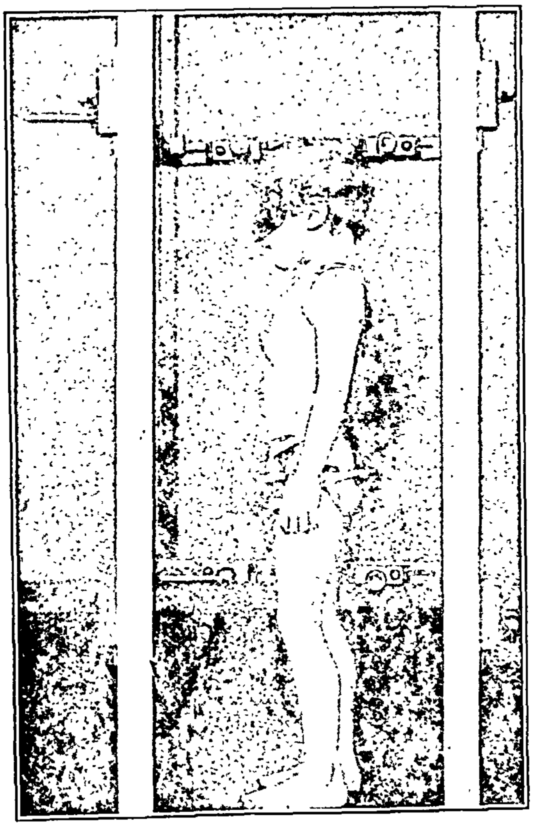

Fig. 2.—Corrected standing position with postural brace, Case 2.

On the other hand, although my experience has not been large, I believe that I have never seen a joint recover complete range of motion or perfect function in which the clinical signs over a considerable period of time were typical of tuberculosis and in which the clinical diagnosis was confirmed by tuberculin reactions, roentgenoscopy or exploratory operation and pathologic examination. I recognize that this experience is at variance with many reported complete cures of tuberculous disease, especially of the hip-joint. My conviction, however, is strengthened by the cases to be reported, which presented quite typical clinical pictures of tuberculosis. All of these to-day have perfect hip-joint motion and perfect function. In all three a carefully done von Pirquet test was absolutely negative, and I am led to believe that a negative reaction is strong evidence that no active tuberculous process of any sort is present.

REPORT OF CASES

Case 1.—*History*.—Girl, aged 6 years, 3 months. Oldest child of a physician, carefully brought up under absolutely hygienic surroundings outside the city. She was first seen six months ago with symptoms in the right hip which had been intermittently present for four months. The family history was good. The past history showed digestive troubles dating back to her first year, continued into her second year, and followed by a more or less chronic constipation and occasional "upsets." During the last four months there had been repeated complaints of pain in the right thigh and the right knee, but never any lasting limp. Three days before being seen she had walked two miles and came back tired, with complaint of pain in the thigh near the knee. Her present illness began on the day on which she was seen. She had started to get up at 5 a. m. to urinate and found it was painful to bear weight on her right leg. There had been no night cries or night sweats. There was little pain at rest or on slight passive movement.

Examination. — The general examination by a careful internist had been negative. The child was poorly nourished, with little color. She stood favoring the right leg, with a prominent abdomen, flat chest, hollow back, forward shoulders, prominent scapulae, pronated feet, and an attitude suggestive of congenital visceral ptosis. The length of the legs was the same. The circumference of the calves and thighs was the same on each side. The motions of the spine and all other joints except the right hip were free and painless. The motions of the right hip were limited, painful and accompanied by spasm in extremes of flexion, rotation and hyperextension. Jarring was only slightly painful. Palpation was negative except for some tenderness to deep pressure over the head of the bone.

A definite diagnosis was withheld.

Treatment and Subsequent History.—Recumbency in the open air was advised, in positions to stretch out the flat chest and tighten the lax abdominal wall. The child was to assume twice a day for five or ten minutes an inverted position with thighs on the low bed and head on a pillow on the floor; mechanical cathartics, liquid petrolatum and agar-agar were ordered, and she was measured for a back brace with abdominal pad to correct the standing position, support the abdomen and maintain proper posture. The pronation of the feet was corrected. For one week the symptoms remained about the same with some diminution of pain and sensitiveness. There developed 0.5 cm. atrophy of right calf. Excellent roentgenograms of the two hips on the same plate and of the two hips singly were negative as to bone disease. The von Pirquet test made a little later was absolutely negative. The child was gotten up with the brace, but without protection to the hip-joint, and exercises to improve her posture and abdominal and back musculature were prescribed under careful supervision.

There was rapid improvement in nutrition and color, together with a complete disappearance of objective and subjective symptoms in the right hip-joint. An appearance of health not before present gradually ensued and was noteworthy. Four months later the patient, after some error of diet, had a severe urticaria and went for several days without her brace or exercises or the assumption of the corrective positions. Within a few days there was an acute digestive upset, but without symptoms in the hip except perhaps a slight guarding.

---

[4] Poncet: Presse Méd., March 26, 1913.

At present she is active, faithful to exercises and positions, wearing the brace half the day, and without subjective symptoms. The right hip has normal motion in all directions. The thighs and calves measure the same on the two sides. The right leg is now nearly a centimeter longer than the left, presumably from the stimulation of epiphyseal growth caused by the toxemic arthritis.

Case 2.—*History.*—Patient of Dr. F. W. Taylor of Cambridge, boy, aged 4 years, 5 months. Oldest child of a man of leisure, carefully brought up under hygienic surroundings in the outskirts of a city. He was first seen five months ago for symptoms in the right hip which had been intermittently present for one year. The family history is negative except that the mother may be described as delicate. The past history showed mild digestive troubles, perhaps not more than in many children, but for over a year the occasional association of pain in the knee with these upsets. This pain usually occurred at night and amounted to typical night cries. There had been no limping in the morning which followed these first attacks of night pain. In the spring of 1913 he had two attacks of bronchitis and croup, and has seemed less well ever since. During the summer, six months before being seen, there had been a very acute digestive upset amounting to almost complete obstruction. Since this time there has been a tendency to constipation. One month before being seen the child had had a slight fall in his play, had limped for a day or two, and complained of pain for a day or two longer. There were occasional night cries as before. Three weeks before being seen he began to limp and to complain of pain in his right leg and knee. The next day he could scarcely walk, but on the day following he was better, and the symptoms gradually passed off. Soon after that he had another attack of croup, and an adenoid operation was advised by an able laryngologist. One week before being seen he had such an acute attack of pain in his right leg that the child screamed when touched and the family physician noticed that the hip-joint motions were greatly limited. The adenoid operation was performed five days before he was seen, and the hip had very rapidly improved while he was recumbent and after the catharsis previous to the operation.

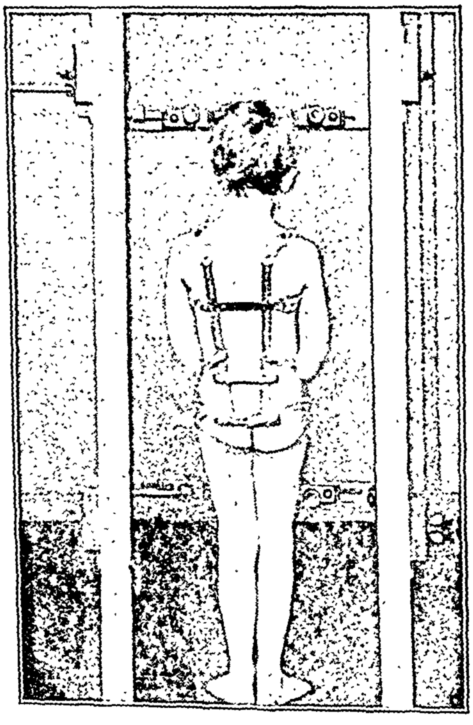

Fig. 3.—Back view of brace to correct posture, Case 2.

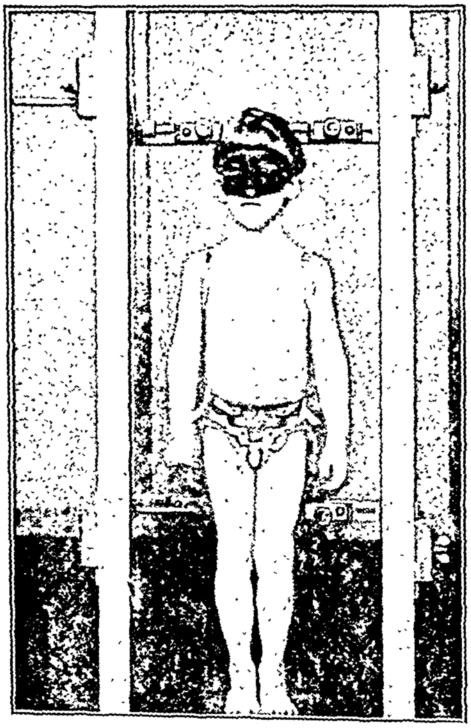

Fig. 4.—Front view of brace to correct posture, Case 2.

Examination.—The general examination by a careful internist, except for the adenoids and enlarged tonsils, had been negative. The child was rather poorly nourished and of poor color, doubtless accentuated by the recent operation. He stood evenly on both legs, with prominent abdomen, narrow, flattened chest, forward shoulders, prominent scapulae, and an attitude suggestive of congenital visceral ptosis (Fig. 1). The length of the legs was the same. The circumferences of the calves and thighs were equal on both sides. The motions of the spine and all other joints, except the right hip, were free and painless. The motions of the right hip were nearly normal, but on careful examination there was distinct restriction and slight spasm in hyperextension and rotation. No sensitiveness to jarring. Palpation was negative.

Treatment and Subsequent History.—The child was not put to bed, but the positions described in Case 1 were shown. Mechanical cathartics were advised and he was measured for a back brace with an abdominal pad to correct the standing position, support the abdomen and maintain the proper posture (Figs. 2, 3 and 4). A moderate amount of weight-bearing was allowed. A provisional diagnosis of toxemic arthritis was made. Roentgenograms taken of both hips on the same plate and of each hip singly were negative. The von Pirquet test was absolutely negative. All the subjective symptoms disappeared, and although the boy had subsequently a second adenoid operation and a tonsillectomy, there was no recurrence of leg pain until about seven weeks ago, when he complained of slight pain in the knee for a few hours, May 2 and 3. He was seen, May 4, but the examination showed normal conditions except for the faintest suggestion of limitation in hyperextension. The boy is now apparently entirely well, with good color, and has had no digestive upsets or sluggishness of the bowels.

Case 3.—*History.*—Girl, aged 14½ months. Only child of people in good circumstances, living in New York City, and referred by a prominent and careful orthopedic surgeon. She was first seen about three months ago and the symptoms had been present for three months. The family history was negative. She had been a bottle-fed baby, great difficulty having been experienced in her early feeding. A proprietary food seeming to agree best, she had been fed on this. After a digestive upset with vomiting, the mother noticed that although she had begun to bear weight and to stamp her feet, she ceased doing so on her right leg, and weight-bearing was painful. When the right leg was raised or moved roughly the child cried. There were typical night cries as well. The family physician was summoned and the orthopedic consultant referred to above was advised by him. The general examination was said to be negative, changes in the diet were suggested in the line of more natural food, orange juice, etc., recumbency and traction were ordered, and a provisional diagnosis of tuberculosis of the right hip-joint made. Within a short time the pain and spasm and night cries having disappeared a short plaster spica was applied by the family physician. This first plaster was worn until three weeks before the child was seen by me, and then a new cast was applied. The family soon moved to the neighborhood of Boston, and the second cast being foul with urine, etc., was removed by a local physician the day before the child was brought to me. During the one night on which she slept without the cast there was no night cry. Since the cast had been applied the digestive upsets had ceased, but the stools had often been hard.

Examination.—The general examination was negative. The baby was well nourished, healthy looking, moving both legs with apparent equal freedom and power. There was no evidence of any sensitiveness or guarding in any of the voluntary movements of the right leg. There were no signs of rickets or scorbutus. The abdomen was prominent, but not tender. As far as could be determined, the legs were the same length. The circumference of the calves of both legs were equal, the right thigh a centimeter smaller in circumference than the left, 8 cm. above the upper border of the patella. The motions of all the joints, including the spine and right hip, were free and painless. Palpation was negative. There was no pain on jarring. During the office visit the child had a movement of the bowels consisting of a hard scybalous mass quite different from the normal movements at this age. Roentgen examination was negative except for a slight thinning of the cortex on the right. The child moved slightly and the examination was not entirely satisfactory.

The final diagnosis was withheld until a von Pirquet reaction could be done, but the possibility of the condition being other than tuberculosis was discussed with the mother.

Treatment and Subsequent History.—The child was placed in recumbency, the bowels were regulated with liquid petrolatum, and the case was referred to a pediatrician for careful examination, regulation of the diet, and a von Pirquet test. No fixation or traction to the right hip was advised. The local physician was asked to make daily visits with his observation directed toward any suggestion of a recurrence of symptoms. The von Pirquet test was absolutely negative. The child was seen again one week later. There had been no noticeable subjective symptoms, although on two or three occasions the child had wakened at night and cried, but not typically as before. The right leg at rest seems to be held in a slightly abducted position. There is no suggestion of limitation of motion in any direction nor any pain on manipulation or jarring. The child has remained well up to the last report.

SUMMARY

No definite conclusions can be drawn from so small a number of cases. They seem to me to indicate the importance of (1) a careful history, (2) a search for possible causes of toxemia, (3) a von Pirquet test and perhaps tuberculin tests with Koch's old tuberculin for the local reaction if the skin test is positive, (4) a provisional diagnosis at the first visit, and (5) the withholding of radical treatment other than recumbency until the diagnosis can be confirmed. They seem to suggest that faulty posture and intestinal derangements may in certain cases have some relation to coxitis.

372 Marlborough Street.

ABSTRACT OF DISCUSSION

Dr. Joel E. Goldthwait, Boston: We must recognize that the physiologic processes of the body on which the nutrition of bones and joints depends should be brought to the highest possible standard, so that the individual may have the greatest possibility of repair. The work of Sir Arbuthnot Lane is suggestive in this connection. When a man of his experience short-circuits the bowel of all children with tuberculosis of the joints caused by general toxemia, and obtains such good results it should make us think. We may not be willing to short-circuit a bowel, when the bowel is already too short in these children, nevertheless, we may make it functionate better, and so stop the toxemia, as Dr. Osgood has suggested. If we examine children, not only with reference to local joint inflammation, but also with reference to the entire body, we shall do well. If we think first of the child as a machine, and consider the disposition of his organs through his standing so badly out of poise, we will see that the normal physiologic action cannot take place. We must build up the resistance by improving the physiologic action, intestinal and otherwise, as well as protect the joints.

Dr. Compton Riely, Baltimore, Md.: Dr. Osgood's paper brings up another question in the diagnosis of tuberculosis, especially tuberculosis of the hip. It shows, I think, that we should be more careful in making our diagnoses of hip-disease. The more of these cases I see, the more doubtful I am of their absolute diagnosis as cases of tuberculosis. We have been taught that if children had pain in the hip, limitation of motion, night cries, etc., they had tuberculosis of the hip; and we used to treat these cases as such, but we must be careful to make a more definite diagnosis in the future. In order to do that we must take time to go through every test and examination that we can think of. If we did this we should find fewer absolute cases of tuberculosis than some of us think.

Dr. Charles A. Parker, Chicago: There is at least one method by which a diagnosis in some of these cases can be reached. This is by learning the causative factor, according to the method of Dr. E. C. Rosenow of Chicago. In osteo-arthritis of the knee he took out the inguinal glands which enabled him to make the diagnosis in twenty-three cases; he found the infectious agent in the blood and teeth, and was able to reproduce the disease in animals. His method of diagnosis will probably come rapidly into vogue. The lymphatic glands are taken from the region drained.

Dr. Frederick Hodgson, Atlanta, Ga.: I confirm Dr. Osgood's observations on these conditions of the hip. Dr. Michael Hoke of Atlanta read a paper some time ago on toxic arthritis of the hip; and since then we have been careful in making these diagnoses at the first visit. We put the patients to bed with the best of hygienic surroundings, use colon lavage and get them into the best possible condition. We find that in this way many cases will clear up.

Dr. W. G. Stern, Cleveland: Reasoning backward from Dr. Osgood's observations, we come to consider the fact that the differential diagnosis of these cases from genuine cases of tuberculous coxitis can be best made by the tuberculin reaction. At the meeting of the American Orthopedic Association in Cincinnati, I reported on a combination of the von Pirquet and the Calmette tests as a reliable guide in making the diagnosis of tuberculous coxitis. I reported cases in which the von Pirquet and Calmette tests were negative in the presence of suspicious joint-pain. One was the case of my own son, who had had, within six months, four attacks of night cries with fixation of the limb in adduction and flexion, muscle spasm and slight limp. Roentgenoscopy and the tuberculin tests were negative and we found that the condition was due to a toxic absorption from the bowel from the ingestion of veal. On cleaning out the bowel and keeping the boy at rest we overcame this condition. Then we gave him some roast veal and brought on another attack. Some persons have an idiosyncrasy to certain kinds of food. In this case the idiosyncrasy was to veal. Since then I have looked for other cases and found one, a year ago, in a girl who presented very much the same posture that Dr. Osgood has shown in his cases. By methods similar to those that he has pointed out a cure has been effected.

Dr. Roland Meisenbach, Buffalo: What applies to children also applies to adults. I had one case in a woman 27 years of age who complained of coxalgia. Hyperextension of the hip-joint was limited on the right side and she also had pain over the region of the appendix, although the surgeon could not find an actual appendicitis. Bismuth oxychlorid was given her in small doses over a period of a week. The symptoms disappeared entirely and hyperextension was regained.

Dr. R. B. Osgood, Boston: Dr. Parker's suggestion is valuable, but it must be remembered that various men have recently shown that these bacteria stay in the blood a very short time indeed. In these attacks, therefore, it would be difficult to catch them in the blood at the time and confirm the diagnosis by means of the glands; and I believe that frequently glands that are causing no trouble will show, by culture, some bacterial growth. Hence, while that suggestion is helpful in cases that we believe represent toxemia rather than definite bacterial infection of the joint, yet I do not think it is of a great deal of use in cases of definite bacterial infection. I was much struck with Dr. Stern's valuable observation of an arthritis of the hip caused by the ingestion of veal.

THE SYNDROME OF ADRENAL INSUFFICIENCY [*]

TOM A. WILLIAMS, M.B., C.M. (Edin.)
Neurologist to Epiphany Dispensary and Freedmen's Hospital
WASHINGTON, D. C.

To the neurologist many cases are referred with the diagnosis of neurasthenia. Many of these are psychologic, being in reality a fixed idea of incapacity derived from the suggestions of medical men or friends, or, perhaps, because of some internal mental conflict which makes the motives for invalidism paramount over those for normal active life. Such patients often actually do become weak, either from mere inaction, or from the malassimilation induced thereby and the worries they permit themselves; this is a familiar picture in a traumatic neurosis,[1] so-called. But among those labeled neurasthenics, there is a certain proportion of patients in whom hysteria is not the factor at all; I do not here refer to psychasthenic patients, in whom anxiety and other features of psychic genesis dominate the picture; nor do I include the *formes frustes* of such psychoses as cyclothymia (manic depressive insanity), hebephrenia, etc. I refer to cases in which definite somatic disturbances are ascertainable, and in which any psychologic symptoms present are dependent on these. Among such cases of "neurasthenia" are persons with latent abdominal or pelvic inflammations, *petit Brightisme*, arterial hypertension and the metabolic disorders which precede it, early stages of cerebrospinal lues, especially that called paresis, and quite often perversion of function of the glands, more especially the thyroid.

Among such cases, I have encountered several in which none of the foregoing conditions were present, but in which the patients were suffering from a profound depression of the neuromuscular functions, quite different from that which is induced mentally or from disturbances of the brain. These are characterized by great asthenia, with lack of concentration, by low blood-pressure, sometimes by psychologic peculiarities, and sometimes by changes in pigmentation. I select a few as paradigms:

Cases may be divided into three classes:

1. Those in which there was improvement or recovery.
2. Those in which there was not.
3. Those which ended fatally.

CASES WITH IMPROVEMENT OR RECOVERY

Case 1.—*History*.—A man holding a high position under the federal government was brought to me by his friend, Dr. Gerrish of Portland, Maine, in 1911. He complained that he was totally unable to bring himself to deal with the responsibilities of managing the situations with which he had to deal, besides which he was greatly depressed mentally and believed that his usefulness was ended. He "can do work if it does not demand responsibility or the handling of men," for he "finds that his judgment one day takes a certain course only to be deflected the next day, even though the facts may be the same." He can make up his mind neither to accept a yachting invitation to Europe he has received, nor to take a professorship he has been offered for next year. He was pale, languid, had flabby muscles and subcutaneous tissues. He had typhoid at 18, and pleurisy at 20. Two years before he had a rise of temperature and a rapid and irregular heart, the cause of which was unknown. He has always taken his work responsibilities very hard. He is a bachelor of a somewhat retiring disposition, which his need for long inspection trips in the West has accentuated.

Physical Examination.—This was negative, except that there was a very slight tremor, the heart sounds were feeble, the systolic pressure was 100 and diastolic pressure 70.

Treatment and Result.—The psychologic situations were entered into with the patient very thoroughly, and it was explained that a simple physical depression from want of adrenal juice prevented the brain from accomplishing the processes necessary for the complex psychologic adaptations which had always caused stress on account of his overconscientious way of regarding his relations with others. He was told that worrying would only aggravate the distress, and that his mental incapacity did not arise from what he feared, impending dementia; it would disappear on rectification of his physical state, the nature of which was explained to him. His diet was regulated and he was ordered much rest along with active exercises in short periods. He was given dried adrenal gland tablets, 2 grains thrice daily. The following week there was an improvement, the systolic blood-pressure was 98, diastolic 70; ten days later the pressures had risen to 114 and 80, respectively, he felt better and looked fresher. The following week after sleeping much, he felt better, but still had no spring; the blood-pressures were 112 and 70, respectively. He was staying with friends, worrying less and clearing up his work preparatory to a vacation in the Maine woods. Just before leaving, two weeks later, his pressures were 113 and 80, respectively; he was now more hopeful and more comfortable in mind; the pulse rate remained 70 throughout.

In the fall of 1912 he returned very much better, the dose of adrenal substance having been reduced until finally he went without it; the blood-pressure runs around 118 and 80, and although he has never completely regained his spring and ambition, he is much better, "feels fit," and has undertaken all the work for the government which he had planned.

Case 2.—A mechanic, aged 57, was referred in February, 1912, by Dr. Jackson; he had done no work after an attack of malaria the preceding September, because he had been very weak and dizzy and had a throbbing in the abdomen. Examination showed a tremor a little like that seen in paralysis agitans, but occurring only on spreading the hands, and a slight tremor of the hands and face; there was slight asthenia, and a hint of von Graefe's sign, especially when he was made to look down rapidly. The blood-pressure was systolic, 108; diastolic, 78; no other abnormalities were found. He was returned to his physician with a reserved prognosis, and a recommendation for massage, a proper standard dietary, and adrenal substance. These measures improved him so much that he returned to work and has been well ever since. His physician says that he has never seen such a transformation.

Case 3.—*History*.—A professor of economics, aged 44, was referred to me by Dr. Newell in March, 1913, because of headaches for six years, especially when tired after using the eyes. Twenty-one oculists had failed to relieve him in this country and in Europe. An internist had found nothing the matter with him. He complains also that at times his whole body is sore, especially the neck, and he often awakes with a pain over the sacrum, dull and heavy, radiating and intermittent, which may be removed for a time by a bath; there is no neuralgia and he sleeps well. It is significant that though he says he cannot work because of the eyes, he easily tires also when read to. He was much worse since grip a month before.

---

[*] Read before the Section on Practice of Medicine at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[*] Because of lack of space this article is abbreviated in The Journal.

[1] Williams, Tom A.: Idea and Emotion in Traumatic Neurosis, Jour. Abnormal Psychology, 1910; Psychic Effects of Accidents, Tr. Southern Soc. Ry. Surg., and Monthly Cyclopedia, 1912, v, 47; v, 650, 722.

The patient had scarlet fever when a sophomore, without kidney disease, followed by insomnia, which recovered while he was a school superintendent in the country. He has no cause for worry, his hygiene is excellent, he formerly exercised much, but now does not feel like it, and loafs a great deal; he lacks sexual desire.

Examination.—This reveals a tired voice, exaggerated reflexes, great tenderness to pressure, and atrophic state of skin and hair, which he says is a family character. Blood-pressure is 114 and 78; there are no morbid psychologic phenomena.

Treatment and Result.—He was ordered massage, active exercise in wood chopping, and adrenal substance, 4 grains twice daily. In a fortnight adrenal was reduced to 2 grains. The only change was the disappearance of hyperesthesia, which I attributed to the massage. After a month, the voice was less tired, thinking and talking were easier, the muscles were stronger. However, headaches were still easily provoked, and asthenopia was still marked; blood-pressure was practically the same. The dose of adrenal was increased to 4 grains again. After this, there was a general improvement, but the patient found that if he extended his work beyond four hours a day he was totally unfit the following day; he was, however, doing a great deal of work in spite of this, even to completing a valuable work on the tariff in time for an insistent publisher. In this respect, he reminds one of Herbert Spencer, who had to limit his work to about four hours a day.

Case 4.—*History.*—A woman, aged 38, was referred in February, 1914, by Dr. Cooper of Hinton, W. Va., because of a postpuerperal psychosis, which greatly accentuated spells of melancholy which she had had for some years. The analysis of these showed that she felt the burden of child-bearing, which she wished to cease; but her husband was a hard man, of rigid views. She was well-developed and nourished, but food had no taste and she had lost interest in life. Blood-pressure was 112 and 84, and there was brown pigmentation of the linea alba, palate and forehead. She was placed at rest in a hospital and massaged and given adrenal substance in a dose of 2 grains twice daily. In a week, blood-pressure had fallen to 106 and 86, and the following day to 90 and 64, respectively. Practically no rise occurred for ten days. Then the dose of adrenal substance was doubled, whereupon there was an immediate rise of blood-pressure until it reached 118 and 94, where it steadily remained for a week even after she left hospital. After this, she went home; and I am informed that she remains well, while the dose of adrenal substance was reduced. She was very difficult to manage, as she desired to leave the hospital and return to her husband, and was obstinately resistant to all reason to the opposite; this idea persisted even after her recovery.

Case 5.—*History.*—A single man of 40 was referred to me by Dr. Bowen, in November, 1912. He was engaged for six months and was obsessed by a feeling that he was disqualified because of impotence. "Worrying about this had run him down so much that he lost his self-control," although he was no longer worried about that; the prospect of marriage in three weeks so horrified him that he no longer wanted to work; he wanted to go and hide; he had the belief that he "was down and out," and that he would lose his job as well. Telling his fiancée had not relieved him in the least, although she was most sympathetic. He had recovered from nervous indigestion some years ago until these troubles came. He had taken many drugs, including chloral hydrate. He was quickly fatigued after a short walk. His physician advised him to marry and go to Atlantic City, but he could not face it, being so "autosuggestible" as he put it; all he could do was to hang around his boarding house, where his fiancée lived.

Examination.—This showed exaggerated reflexes, small pupils, sunken eyes, very large, soft, weak pulse without cardiac dilatation, pigmented abdomen, and blood-pressure 102 and 80. Psychic examination was gone into most thoroughly, but it showed no important features, there being no night terrors, and the dreams, whether pleasant or unpleasant, not having pathologic significance. He was prescribed adrenal gland and wet packs to induce sleep. Three days later, the packs not having been taken, the blood-pressure was 100 and 80. The cooperation of his fiancée was enlisted, and his physician reports to me that he fully recovered and married; but I have not ascertained his present blood-pressure.

CASES WITHOUT IMPROVEMENT

Case 6.—*History.*—An ethnologist, aged 30, was referred by Dr. Henning, in February, 1914, because, as he put it, "his mind feels as a shadow only, and for two years most of the time nothing seemed real." The condition had begun suddenly two years ago, from what was believed autotoxication. He first noted it while doing professorial work at Columbia University when he could not clearly focus his thoughts, and was very much alarmed at it. As a matter of fact, he was a good deal concerned about his physical health for some years, having intestinal flatulence especially after worrying, which he did much; now and then he would have a foul tongue, severe indigestion and dizziness, and headaches in the morning, and he had attributed his condition to disordered metabolism. A love affair aggravated his condition; but this was duly settled by his marriage, which, however, did not improve his health.

He consulted a New York neurologist, who laughed at him and said his nerves were disordered, and ordered a vacation, which he took without benefit. He had a weak, heavy feeling, especially in the arms, and sudden insomnia without cause. During field work among the Indians in Oregon he began to feel better for a while, but finally became so ill that he went into a sanatorium, where a diagnosis was made of a psychoneurasthenic. There he gained 20 pounds, and felt practically well for a few weeks. Returning East in the train, he caught cold, and lost 8 pounds in ten days. Since then, three months before, he has felt out of sorts a great part of the time.

Examination.—The reflexes were slightly exaggerated, the frontalis reflex very markedly (this is obtained by tapping over the zygomatic ridge just in front of the antitragus, when a sharp twitch of the eyebrow occurs). The tongue was flabby and white, except just at the tip. The blood-pressure was 102 and 78; the patient was very swarthy, as he said he had always been. Moderate smoking and some constipation were the only other features noteworthy.

Treatment and Result.—The patient was given a standard dietary, massage and adrenal substance, 2 grains per day. In ten days the blood-pressure had become 108 and 86; he was irritable, had sinking spells in the chest, felt presentiments, started in his sleep at times, his eyes ached, and his feet become cold. He was sent to bed. Two weeks later, after being up two days, the blood-pressure was 90 and 68, and he felt very tired; his mind was not clear and there was pigmentation of the palate. The dose of adrenal substance was doubled; he was given one tablet of thyroid substance daily in addition. Three days later, the pressure was 104 and 78, and he was found to have increased 5 pounds in weight. Wood chopping was prescribed, and later on the blood-pressure was 117 and 88; but he felt bad. Four days later the blood-pressure was taken by Dr. Lemon, whom I had asked to cooperate in his care, when it was reported to be 112. The next day, after a sleepless night and a day of work, it was 98 and 68, and he had lost 2 pounds. I found he had taken no adrenal substance for five days because he had vomited after taking a decomposed portion. Eight days later the blood-pressure, taken by Dr. Lemon, was 100; three weeks later, 110; the next day, 110 and 78. The patient had been at work typewriting some notes, for he could do no thinking. A week later, blood-pressure was 100 and 82, and the pulse was very weak; he was prescribed 14 grains of adrenal substance per day. He thought it made him feel ill and gave it up; four days after, the blood-pressure, taken by Dr. Lemon, was 110. A week later, blood-pressure was 100 and 65, respectively, since when it has varied between this and 110. Meanwhile a blood examination was made by Dr. John Nichols, which was as follows: Red corpuscles, 5,900,000 per cubic millimeter; hemoglobin, 85 per cent.; corpuscular hemoglobin ratio, 0.72; leukocytes, 13,300 per cubic millimeter; proportion of white to red corpuscles, 1:440; small lymphocytes, 33.3 per cent.; large lymphocytes and large mononuclears, 8.3 per cent.; polymorphonuclears, 43.7 per cent.; esoinophils, 13.7 per cent.; mast cells, 1 per cent. The large proportion of eosinophils caused us to look for intestinal parasites. The examination of the feces was negative, and we are at a loss to account for this phenomenon.

The only result of the treatment is that the patient is now worrying a good deal less, and I am in hopes that he will learn to content himself with a good deal less output of work, that his functional inadequacy will not increase, and that a slight improvement may occur from the large dose of adrenal substance that we are now giving.

CASES ENDING FATALLY

Case 7.—*History.*—The 17-year-old daughter of a Boston physician, a brilliant girl, began to tire easily both in study and in play. She was recommended a long rest; so her father took her a trip to Europe, during which, however, she became more and more unable to respond to the interests of the visit; finally she was brought to visit an old friend in England at a private institution where I was making some psychologic studies; there I was asked to see her in consultation with the superintendent. By this time the asthenia was extreme, the pupils were dilated, and the bronzing of the skin most decided, so that the diagnosis of extreme hypo-adrenalism was manifest. The psychologic history was imperfect, as we were exceedingly anxious to improve the condition we found. Adrenal substance was given, both in the mouth and under the skin; but there was no response, and within a week the little girl died. Of the blood-pressure, I have no note; I do not think there was an instrument at that time, 1907, in the institution. The adrenals were taken out post mortem, and were found almost free of gland substance, nothing but some medulla and the capsule being left. A careful histologic examination showed no sign of inflammation, and we had to conclude that we were dealing with either a simple dystrophy or an autolysis of toxic origin.

DR. SCOTT'S REPORT

"Paraffin sections from two pieces were cut, and stained originally with eosin and Ehrlich's acid hematoxylin, more recently by hematoxylin and Biebrich scarlet method (Scott, 1912).

"Microscopically, the capsule is relatively thick, and surrounds a central region infiltrated with lymphocytes, and in some parts engorged with blood. Among the lymphocytes are large cells of irregular shape, with basophil cytoplasm and nuclei of variable size. These cells are frequently arranged in strands. In some places are a few cells whose cytoplasm is somewhat oxyphil (really amphophil with oxyphil preponderance), and whose nuclei are on the average smaller than those of the basophil cells. In some of the more recent sections an accessory cortex whose cells are like those of the second group is visible, lying in the capsule.

"Originally, before I had seen the accessory cortex, and being also more ignorant than I should have been, I was unable to determine the origin of the cells described above. At the present time it is quite clear that the first group is medullary and the second cortical, for by my method the cytoplasm in the medullary cells is predominantly basophil, and in the cortical cells predominantly oxyphil. Everywhere some of the cells have a degenerate appearance, even in the accessory cortex. To sum up, the cortex is practically all gone, but the medulla is much less destroyed.

"The process appears to be centripetal degeneration of the suprarenal cells, accompanied by lymphocytosis and patchy engorgement with blood. Unless pure lymphocytosis be inflammatory there are no signs of inflammation. Certainly there was no fibrosis going on at the time of death, in spite of the thick appearance of the capsule. This relatively thick capsule must be the original capsule and the scanty connective tissue of the cortex collapsed together after disappearance of the cortical cells; for if new formation of white fibrous tissue were going on, young fibroblasts would be present, and their cytoplasm would be obvious, being basophil. As it is, the connective tissue cells have unstained cytoplasm. I should like to emphasize this characteristic of fixed connective-tissue cells, namely, that when they are young, as in the fetus, granulation tissue and spindle-celled sarcomata, their cytoplasm is basophil enough to stain with Ehrlich's acid hematoxylin; but when they are mature they appear as naked nuclei, the cytoplasm being no longer sufficiently basophil to stain as before, nor sufficiently oxyphil to take up the acid dye."

Case 8.—*History.*—A married woman of 34, formerly a schoolteacher, was referred to me by Dr. Wilson on account of a nervous breakdown thought to be the result of twelve years of overwork, during which her weight had fallen from 114 to 97 pounds. She had been worse since her marriage three years before; she had not benefited from residence in a sanatorium or a removal of a uterine polypus. She had been anemic, and although she ate well she did not seem nourished. The heart was feeble. She was a woman of extraordinary good sense and did not worry; she had suffered all her life from inherited menstrual headaches which had prevented her rest; she used to have numbness in the leg; now even massage tires her.

Examination.—This showed feebleness of the reflexes, the abdominal and plantar being hardly perceptible; dilatation of the stomach, râles in the chest, pale mucous membrane, sunken eyes, and with it all a calm psyche. Weight was only 83 pounds; there was earthy brown pigmentation on the face, linea alba, a splotch below the xyphoid, and a faint discoloration on the arms and legs, while the coccyx and buttocks were very dark. Hemoglobin was 80 per cent., red cells 4¾ million, leukocytes 3,000; the systolic blood-pressure was 86 or less and the diastolic 66; it was difficult to measure. A week later, the pressure was 80 and 64, the reflexes needed reinforcement and her weight was 81 pounds. She went into the care of Dr. Marbury, and some weeks later she died. Necropsy was refused. It is impossible, therefore, to say whether the failure of adrenal secretion which caused her death was due to tuberculosis, as is often the case, or was a simple atrophy, as in the preceding case.

DIAGNOSIS, DIFFERENTIAL AND PSYCHIC

From conditions of physical causation characterized by great fatigability and feeble circulation the diagnosis would of course be made by the current procedures of clinical medicine, on which I need not enlarge here.

PSYCHASTHENIA

But the diagnosis from certain neurotic states requires specification. Patients of the type I have described are often labeled psychasthenics because of their *feeling* of inadequacy, the most prominent feature in psychasthenia. But the genesis of this feeling in hypo-adrenalism is a real physical tire occurring only during exertion, while the genesis of the inadequate feeling in psychasthenia is from a besetment or apprehension; and it always passes off while the patient is actively exerting himself with muscles or mind. If there is any feeling of panic because of the dread of his incapacity in a hypo-adrenal patient, this is a purely secondary and normal reaction to *physical fact*; and it is very easily dealt with by enlightenment, as my cases illustrate. Furthermore, *psychasthenics* present a vast series of intellectual, emotional and often motorial symptoms, the combination of which is characteristic, and the source of which can be detected by analysis of the psyche.

HYSTERIA, NOSOPHOBIA AND HYPOCHONDRIASIS

The seeming exhaustion and asthenia so often found as a result of a patient's belief *in* the malfunctioning of a stomach, heart, intestine, limb or brain is a phenomenon of mental attitude induced in the same way as is the case in the little child who suddenly becomes tired when his work or play is no longer to his liking. It is merely a lack of the toughening of psychologic fibers necessary to social welfare. It is a phenomenon induced by suggestion, and its name is hysteria. The real physical exhaustions which may occur after long continuance of hysteric attitudes like this are secondary to the depressing emotions sometimes induced in the patient's mind.[2]

From *melancholia* the incapacity of hypo-adrenalism is distinguished by the absence of the retardation of thought and movement always present in the true melancholic, in whom, furthermore, the responsiveness increases in speed and effectiveness as the day goes on and when the stimuli are augmented and longer continued, whereas in hypo-adrenalism the patient is at his best early in the day and the more work he does the worse he becomes.

Concerning *neurasthenia,* it should be evident that I have ceased to recognize any such nosologic rubric, regarding the term merely as a convenient cloak for failure to investigate a case sufficiently, and placing all the patients who were thus formerly diagnosed in categories corresponding to the etiologic factor which has determined their condition.

PATHOGENESIS

That prolonged hyperfunction may play a part in the etiology of hypo-adrenalism may be inferred from the facts furnished by posthyperthyroid myxedema (Wilson) and posthyperpituitary adiposity (Cushing and others). That hyperfunction of the adrenals may be induced psychologically is certain from the experiment of Cannon, which shows that the adrenal vein after fright contains a greatly increased amount of the secretion of the gland. The work of Crile too tends toward the belief that the form of prolonged fright known as anxiety may produce the same oversecretion as it undoubtedly does in the case of the thyroid gland.

Now both fright and anxiety are psychologic in induction; they are derived from ideas, an attitude of mind, which may be maintained from within by cogitation by animals with memory long after the disappearance of their initial cause. So that the conditions for the maintenance of that which makes for adrenal hyperfunction are ready in human beings to be called into action at all times, in those persons whose early training has increased fears and scruples about conduct and life.[3] It is only by proper, which means profound, analysis of the features which lead the clinician to penetrate to the foundations of human feelings and behavior that these patients can be understood, and the responses of their organism can be thereby "reconditioned" into health-bringing reactions. The way of doing so, true psychotherapy, is only an elaboration of the method employed by Pawlow to condition the vegetative reflexes of dogs.[4]

CONCLUSION

The cases reported, and the considerations involved, are far from completely presented, and I am well aware of this; but a consulting neurologist without the hospital facilities for research on a large scale is not well fitted to elaborate what is a very complex problem, namely, pathogenesis, complete clinical syndrome, and treatment of hypo-adrenalism. Although it would seem that prolonged psychic strain plays a part in the induction of the condition, yet on the one hand, thousands of individuals undergo long psychic strain and retain their adrenal sufficiency; indeed, perhaps, functionate excessively in that respect, while on the other hand, it is hardly credible that the adrenal inadequacy from which the Boston physician's daughter died was due to any excessive strain. We are reduced, then, to the hypothesis of the general inadequacy of the chromaffin system to explain cases of this kind. It may, indeed, be that inherent inadequacy is responsible for the failure of the adrenals in all cases in which there is no inflammatory or toxic process damaging the glands. I commend the problem to the resources of some large clinic. My paper is presented mainly in the hope of again drawing attention to the need of differentiation, even in a group of cases most typically neurasthenic.

PATHOLOGY

According to Scott,[5] Addison's disease must be due to loss of cortex, for accessory cortical tissue is a variable quality; but with so much other chromaffin tissue in the body, loss of the medulla should not be particularly harmful. On searching through the literature it appears that several similar cases are on record, details of which will be found in the works of Simmonds,[6] Karakascheff[7] and Bittorf.[8] Of these, some have the medulla intact, but the cortex gone, others have more or less cortex and medulla left, and yet others are merely fibrotic. Karakascheff,[7] working in Marchand's institute on specimens very similar, was, I believe, the first to prove destruction of the cortex to be responsible for Addison's disease. That the medulla is not essential to life is seen from his case of a child, 5 to 6 months old, in which the cortex was intact, but the medulla had been destroyed on both sides by hemorrhages, but so long before death that calcification had taken place. During the patient's stay in the hospital no symptoms were observed which were referable to the suprarenals. To show the importance of the cortex, he also brings forward a case in which, after death from other causes, one suprarenal was found to have been destroyed by tuberculosis some time previously and the other was hypertrophied, but in the cortex only, thus corresponding with the results obtained by previous workers after removing one suprarenal in young rabbits and guinea-pigs. Wiesel[9] studied ordinary tuberculous cases of Addison's disease, and found that the chromaffin tissue outside the suprarenals was also diminished in amount. He came to the conclusion that Addison's disease was due to deficiency of the whole chromaffin system; but it is hard to understand why tuberculous destruction of suprarenal medulla should be accompanied by simple disappearance of other chromaffin tissue, rather than by compensatory hypertrophy. His cases also all showed more or less destruction of cortex. In a second paper, Karakascheff (1906) is unable to confirm Wiesel's observations on general loss of chromaffin tissue, and deals with the well-known finding of destruction of suprarenals without Addison's disease. This he ascribes to the presence of a sufficient amount of accessory cortical tissue, and he further gives a detailed description of two such cases.

ABSTRACT OF DISCUSSION

DR. FRANK R. STARKEY, Philadelphia: In dealing with conditions in which the organs of internal secretion are involved, we must remember three things; first there is no such thing as a syndrome of adrenal insufficiency or of thyroid or pituitary insufficiency. This condition is always polyglandular or multiglandular. Although any of the organs of internal secretion may be most conspicuously involved, including the sexual organs, whether the condition be one of lowered function or excessive activity, the condition is always multiple. When one of the group is not functioning properly, the equilibrium of the entire chain is disturbed and the delicate balance normally existing between them is destroyed. Adynamia, inefficiency, mental and physical asthenia and melancholia are the keynote of this condition no matter what name we give the syndrome. Secondly, because of the multiple nature of the condition we must treat the entire group. Thirdly, it is a mistake to administer extracts or other products obtained from spayed animals. The glandular products of commerce are all derived from animals which have been raised for food purposes and they have been castrated in their early youth to improve their flesh for food purposes and they are neurasthenic and inefficient themselves. I do not know just why the medical profession has not recognized this before, for the difference in the texture and flavor of the flesh as well as in the temperament of these animals is so well known. The change from the bull to the ox or from the cock to the capon are conspicuous and familiar examples. The change that takes place in their organs of internal secretion is just as marked, so that the chemical composition and the physiologic action of glands obtained from spayed animals is very different from that of those derived from unspayed ones. In melasma or exophthalmic goiter, it is good organotherapy to treat all of the glands of internal secretion. We must bear these points in mind if we are to be successful in organotherapy.

DR. WALTER L. BIERRING, Des Moines, Ia.: I will refer to a case of melasma, the patient being the wife of an Iowa physician. She is 37 years old, and the mother of two healthy children. The condition has been observed about two years, and at present the pigmentation and hypotension are marked. The systolic pressure is 70 and the diastolic 45 mm. Hg. She is fully conscious of her condition, and therefore observant of symptoms and the effect of different plans of treatment. She feels that she is entirely sustained, and in fact her comfort depends on the taking of adrenal extract in doses of 3 grains three times a day. When in a state of extreme weakness, with an absent radial pulse, a single dose will bring back a palpable pulse, raise the blood-pressure appreciably, and increase her general strength. I agree with Dr. Starkey's remarks with regard to adrenal insufficiency as but a single factor in promoting the condition usually referred to as Addison's disease (melasma), because as in the case referred to, while life is sustained and an improvement of symptoms takes place under the substitution therapy, a cure of the condition by this means alone is not to be accomplished.

DR. TOM A. WILLIAMS, Washington, D. C.: I wish to thank Dr. Starkey for his hint concerning the extracts from nonspayed animals; but I cannot agree with the generalization that all endocrinian disorders are pluriglandular, although I have had many such mixed cases. The cases reported in my paper were specifically chosen because they seemed to represent the syndrome of adrenal insufficiency in its purity. Furthermore, in the cases which did not improve, mixed-gland therapy was ineffective; but I cannot say why the extra large dosage should prove conspicuously effective in one case while failing to assist others. I have brought the subject before this Section rather than that of neurology, in order that others may be encouraged to make more extensive and thorough observations than are possible for a neurologist without a large hospital service.

PAPILLOMA OF THE LARYNX *

HARMON SMITH, M.D.
NEW YORK

ETIOLOGY AND HISTOLOGY

Many papillomas spring from an inflammatory, syphilitic, tuberculous or even a malignant base, and histologically the malignant are but an exaggerated and continued form of the benign papilloma. A beginning hyperplasia on the vocal cord, irrespective of its underlying cause, may in due course of time assume proportions, varying from a small papular mound to a mass of epithelial growth filling the entire larynx. The proliferation in all cases is chiefly that of the epithelium, although there will be found fibrous thickenings occupying largely the posterior laryngeal wall and the posterior half of the vocal cords, which are seen quite frequently in habitual consumers of alcoholic beverages, also in newsboys, peddlers, hawkers and in those suffering from chronic or atrophic rhinitis. In singers, particularly those with soprano or tenor voices, these thickenings of the epithelium occur on the anterior third of the cord, and are the result possibly of muscle strain. From these hyperplasias spring pointed projections, which form the so-called papilloma. The surface may be papillary or may be smooth with but slight irregularities. The color may vary from a pale, dead white to a red or rose color; sometimes they are dark gray, at others the same color as the cord. Often they are mistaken for singers' nodules, particularly when located at the anterior third of the cord on its border; they may be single, broad-based, multiple or pedunculated with slender bases and vibrate with the respiratory current. They occur frequently in children as a mass filling the larynx, crowding one on the other, some with broad bases and others with pedunculated bases. The simple flat papilloma has but few branching projections, usually very white, with a surface cornification such as is seen in the hard, dry wart on the hand.

This type is observed in elderly men and should be regarded with suspicion, particularly if there is increased vascularity at the base. Often the microscope will reveal no indication of malignancy, as the bits of epithelium removed from the surface of the growth give no evidence of the character of the substratum; but later examination will define the malignant character of the underlying structure.

The frequency of papilloma as compared to other benign growths varies from 39 to 50 per cent. of all cases of benign laryngeal growths. When appearing singly, their most frequent locality is in the anterior half, while the multiple variety will be found most frequently in the posterior part of the larynx, but may also extend to the rest of the mucosa. In children, papilloma is the most frequent laryngeal growth and has been known to be congenital. Here they appear in the branching or budding form and may spring from

---

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

the entire laryngeal mucosa. In the greater number of instances they reappear persistently when removed until such physiologic change takes place in the child as will occasion their permanent disappearance.

SYMPTOMS

A small papilloma may exist on the vocal cord of an adult for a long time without attracting the attention of the individual or his associates, either by local discomfort or alteration in voice. In fact, singers have been able to continue their professional work with a moderate-sized papilloma on the cord, without noticeable alteration, except perchance a failure to produce properly one particular note in the limits of their vocal register. In the majority of instances, however, the most noticeable symptom of the existence of papilloma of the larynx is a husky voice or some deviation from the normal. Hoarseness, with now and then a falsetto note, or the reduction of the voice to a subdued whisper is most marked in the adult. The single papilloma when situated on the anterior third of the cord will produce considerably more vocal disturbance than when situated elsewhere. In the multiple variety, particularly in children, the voice is often reduced to a low, hoarse whisper and the cry of the infant, when multiple papillomas are present, resembles that squeaky sound often noted in cases of croup or acute edema of the larynx. The child is often dyspneic and under exercise may become cyanotic. During excitement the facial expression assumes a peculiar aspect denoting insufficient respiration. The same condition is often seen in children in whom large lymphoid masses exist both at the base of the tongue and in the nasopharynx, but when hoarseness has been a prevalent symptom in the child over a continued period, although tonsils and adenoids are sufficiently hypertrophied to warrant the supposition that they are responsible for the hoarseness, it is nevertheless advisable to bear in mind the possible existence of papilloma. In children the long continued presence of papilloma causes irritability, impairs digestion, narrows the chest by insufficient respiration and incidentally reduces the vitality owing to improper oxygenation of the blood. They become pale, anemic and emaciated, although exceptions to this rule are often seen, when the child is fat, thick-necked and of good color.

FREQUENCY

Judging from the reports formerly submitted by Fauvel and others, we can reasonably conclude that in the early history of laryngology more of these neoplasms existed than at present. The reason for this lessening in frequency may be attributed, according to Wright, to two cause:

> First, the number of trifling laryngeal complaints which come under the observation of the laryngologist to-day has enormously increased; second, to-day treatment in these cases, but especially early and judicial treatment of nasal and pharyngeal diseases has greatly cut down the liability to inflammatory benign laryngeal neoplasms.

Their occurrence in children is comparatively rare. Clark found only twelve cases in the examination of 12,623 children under 14 years of age at the Massachusetts General Hospital. Over a period of fifteen years there have come under my care and treatment at the Manhattan Eye, Ear and Throat Hospital only eight patients, and I have had occasion to observe in the clinics of my confrères only a few additional ones. In 300 tumors of the larynx reported by Fauvel, 206 were papillomas, and of this number nine were in children under the age of 15 years. In the reports of 302 cases of combined papilloma and fibroma of the larynx, 209 occurred in men and 93 in women, thus showing a preponderating tendency of this growth in men.

TREATMENT

Laryngofissure was at one time believed to be effective in the removal of these growths and in the prevention of their recurrence, but the experience of many operators has demonstrated that this is not only ineffective in the majority of instances, but permanently injures the voice, so that it is now deemed an absolutely unjustifiable procedure. Abbey reports a case in which thyrotomy was performed four times, with recurrence of the growth after each operation, although the bases of the tumors were cauterized; tracheotomy had finally to be done ere the condition was overcome. Lindon reports a case in which thyrotomy was performed seventeen times; but the case finally resulted in laryngeal stenosis, necessitating permanent use of the tracheal tube. In adults, removal of the growth either by indirect or direct laryngoscopy offers fair hope of its eradication, although in many instances recurrence takes place even though the base is cauterized. In the multiple variety in children, surgical removal by direct methods not only results in recurrence of the growth at the site of operation, but likewise occasions new growths to spring up on adjacent mucosa, even on the epiglottis, aryepiglottic folds and trachea. Occasionally in children the growths may be removed by the direct method and the bases fulgurated, and the operator be able to keep ahead of the recurrence of the growths until such physiologic change takes place as will result in their permanent disappearance. In this way the necessity for a tracheotomy-tube may be obviated. Fulguration will result in the disappearance temporarily of the growth, and the recurrence is postponed longer than when operative measures alone are employed; but fulguration has been disappointing as a permanent and positive relief for these growths in children. About the time of puberty or in adults the tendency to recurrence is markedly less, and removal either by fulguration or instrumentation presents more favorable prognosis as regards recurrence. To apply the fulgurating spark with sufficient intensity to be effective it is necessary to have the cauterizing point well insulated to prevent short-circuiting with the metal laryngeal spatula. It is also necessary to have the larynx as free from secretions as possible, as the wet mucous surface tends to disseminate the spark so that its concentration on the growth itself is ineffective. It is also necessary to bear in mind that ether and chloroform fumes are highly inflammable and the child should be permitted to breathe for a half minute at least after the anesthesia is removed ere the fulgurating spark is applied.

In some of my cases I have been able to apply the fulgurating spark with cocain anesthesia alone and I believe this to be the better method if the child is at all tractable. The fulgurating tip should be placed directly on the wart before the spark is turned on and also the current shut off before the point is removed; otherwise the current will be transmitted to the metallic speculum. When a proper spark has been obtained in the larynx the transmission of light may be seen externally, and a good illumination is observable simulating that of transillumination of the sinuses. Unless fulguration is excessive no edema or other untoward symptoms result, and the larynx may be entirely cleared of its neoplasms at one sitting, provided the secretions and the tractability of the child permit its continuance. In one or two instances, however, I have seen considerable edema follow fulguration. In one case (Case 3), particularly, the larynx began to swell almost immediately after the application of the spark, but in this instance my associate, Dr. MacPherson, desired to be very thorough as the parents wished to remove the child to another city, and we hoped to get rid of the growths entirely by the one application. The edema following the fulguration was so threatening that it was deemed advisable to do a tracheotomy. In the other cases, however, there were no indications of dyspnea, cyanosis or any evidence of pain on the part of the patients. The best surgical method for these cases and the one method which is most invaluable in meeting the requirements of multiple papilloma in children is tracheotomy. This was recommended years ago by Hunter Mackenzie, and with the exception of a few cases has proved a most efficient therapeutic measure.

Tracheotomy, *per se*, is virtually without danger, particularly if all surgical precautions are employed and the child is placed under a croup tent for a few days subsequent to the operation. It is necessary for the child to wear this tube for a period varying from six months to two years, depending largely on the age of the patient and the time necessary for the physiologic change to take place, which eventuates in the disappearance of the growths. I have seen one case in which marked fibrosis resulted from the frequent removal of a single papilloma in the anterior commissure of the larynx, and from the anterior border of this fibrosis a large single papilloma projected out between the vocal cords. This case had been under observation for a long period of years, but both fibrosis and papilloma disappeared between one visit to the clinic and the next, a period of about two weeks. It demonstrated beyond question the conclusions advanced by Dr. Jonathan Wright a few years previously, based on observations of the same case, that a physiologic change would at some time occur when this growth would disappear. In accordance with his prognosis, not only the papilloma but the fibrosis disappeared within a period of a month, so that the voice became almost normal.

RADIUM

Radium has been applied in a number of instances, and in some cases marvelous results have been obtained. Abbey reports a case in which the application of 100 mg. of radium kept in position for one-half hour resulted in the rapid disappearance of the growth. Similar experiences have been related by Harris and Culbert. In my experience, however, there is one case presenting sufficient interest to warrant a detailed account, not yielding to radium.

CASE 1.—A. V., aged 15, had from birth a husky voice, leading to the supposition that there were congenital growths in the larynx. When about 5 years of age he was operated on by Dr. Culbert for multiple laryngeal papilloma associated with the characteristic symptoms. Laryngofissure was performed at that time and the entire contents of the larynx cleaned out and the mucosa was cauterized. Within two weeks there was noticeable improvement, which improvement lasted for about six years. At the end of that time there began a recurrence of the symptoms such as hoarseness, dyspnea and imperfect voice production. As this continued to increase he came to my clinic at the Manhattan Eye, Ear and Throat Hospital, Sept. 19, 1911, at which time there could be seen a number of warts on both sides of the larynx, both anteriorly and posteriorly. The voice was very imperfect and of a hoarse, whispering character. The evidence of the former laryngofissure was observable and the movement of the larynx was somewhat imperfect. A tracheotomy was performed and the tube worn for the space of nearly a year. The growths were removed under cocain anesthesia by the direct method, it being reasonable to suppose that surgical removal at this stage, when the patient was approaching puberty, might result in a permanent eradication. They recurred with regular frequency. It was later determined, April 23, 1912, that fulguration should be tried without surgical interference. The growths disappeared following the fulguration and the necessity for another seance did not occur for a period of three months, when they were again removed in the same manner. They recurred again at the end of two months, when the third application was made. This time they recurred at the end of a month. After each fulguration, however, a less number of growths returned and the right side of the larynx cleared up almost entirely. The persistent fibrosis together with a large sessile papilloma remained on the left vocal cord and ventricular band. The obstruction to laryngeal respiration, however, was so slight that the tracheotomy-tube was removed in October, 1912, since which time local treatment and rest together with partial removal of the growth, whenever it encroached on the larynx, has followed. This procedure was carried out in the belief that the boy was approaching that physiologic change incident to puberty which would result in a permanent disappearance.

Radium Treatment.—As this did not take place it was decided in March to employ radium. Through the kindness of Dr. Wolf Freudenthal a tube of radium was placed in the larynx after cocainization, March 19, 1914, and left in for about three-quarters of an hour. There appeared to be a disappearance of some of the thickening around the growth.

March 26, it was again applied for a period of about one-half hour following which there seemed to be a marked reaction. The voice has improved under the application of the radium, but the growth continues to recur. There have been three additional applications of radium, varying from fifteen minutes to three-quarters of an hour, but so far as clinical observation goes there has been no diminution in the size of the growth. The boy is in good health, speaks with a hoarse voice, and while the radium has apparently had little or no effect on it, my belief still holds that physiologic change will ultimately bring about that which therapeutic measures have failed to accomplish.

Delavan suggested years ago the employment of alcohol locally applied for the cure of papilloma of the larynx, and in many instances it has proved effective. I have applied it in a number of cases of papilloma of the larynx in children without any apparent effect, but here their multiplicity and the large area of mucosal involvement naturally lessen its effectiveness. In adults, the conditions are entirely different and the shrinking and drying properties of alcohol tend to bleach and dry the superficial epithelial surface so that it might disappear by autoclysis as the tonsil does with increasing age.

Shurly has recommended the employment of *Thuja occidentalis* locally and internally. This also failed in my cases of multiple papilloma of the larynx in children. Castor oil, sodium salicylate, zinc chlorid, silver nitrate, iodin and various other therapeutic agents I have tried persistently, but without any apparent effect. In my first series of cases, reported some years ago, the last case of the series had been persistent in the return of the warts when removed by the direct method and had not responded to tracheotomy, although the tube had been worn over a year. One application of the fulgurating spark resulted in their immediate disappearance, from which I concluded that fulguration would be the solution to the problem. Subsequent experience, however, has disabused my mind of this hope as by fulguration the growths can be immediately and effectively removed; but they return with the same regularity as when removed by surgical means, although the length of time intermediate between the destruction of the growth and its reappearance is longer.

From the fact that in some instances of multiple papilloma of the larynx removal will result not only in the reappearance of these growths in their former situation, but likewise on adjacent mucous membranes, it has occurred to me that there might be an infectivity embodied in certain of these growths, in which, if an emulsion were made of the growth itself, hypodermic injection might prove beneficial in their complete eradication. Since giving expression to these ideas on several occasions no case has presented itself in which a sufficient quantity of the growths could be obtained for this purpose. It is a well-known fact, however, that not only laryngeal warts but skin warts will reproduce themselves on abraded skin or mucous surfaces in some instances and not in others.

SEQUELS

Barring the few unfortunate instances in which wearing the tracheotomy tube over long periods of years has not eventuated in the disappearance of the papilloma, the prognosis is favorable to their disappearance. The voice, however, in the majority of instances is altered in some degree and probably in children in whom multiple papillomas have existed it may never attain perfection thereafter. In isolated, pedunculated papilloma on the vocal cords of the adult removal is ordinarily followed by complete restoration of voice. When the tracheal tube has been worn for a year or more the cartilaginous rings lose their elasticity and one the withdrawal of the tracheotomy tube the trachea collapses on inspiration. This may be largely obviated by frequent withdrawals of the tube during the course of the treatment, so that the tracheal rings may expand and contract during the respiratory act. When the time has arrived for the permanent withdrawal of the tube it is often advisable to insert tubes diminishing in size until the minimum-sized tube has been reached, after which time it is sometimes necessary to insert a rubber catheter until the larynx and subglottic structures have resumed their normal resiliency. A straight tracheal tube, with just sufficient flange at the end to hold it within the tracheal incision, is often better than one which is curved and extends far down into the lumen of the trachea, for in this way the thickening incident to friction against the tracheal mucosa is obviated. In cases of multiple papilloma in children after tracheotomy has been performed, close observation will reveal these growths extending into the upper part of the tracheal wound and impinging against the tube. I have seen the entire space between the tracheal wound and the larynx almost completely filled with these growths following operations on the laryngeal neoplasms. Occasionally there will result the necessity for a plastic operation to close the tracheal wound completely, but in the majority of instances the withdrawal of the tube will be followed by the wound closing by granulation.

REPORT OF CASES

Case 2.—An Italian boy, aged 7, presented himself at my clinic in 1909 complaining of hoarseness from birth. Examination of the larynx revealed multiple papillomas. One of the papillomas was removed for microscopic examination, and a syphilitic base was revealed. One injection of salvarsan resulted in the complete disappearance of all the growths, within about three weeks time. The voice was not restored, but was markedly improved from a hoarse whispering voice to a hoarse loud voice. About two months after the injection of salvarsan the boy was brought to the clinic suffering from pronounced jaundice, which did not respond to treatment. His condition became worse until he died about three weeks after observation. No necropsy was permitted. Treatment for his inherited syphilis was instituted at a time when large single doses of salvarsan were being administered, and I have often wondered if repeated smaller doses would not have resulted in the same favorable outcome to the laryngeal condition and possibly obviated the liver complication.

Case 3.—J. S., a boy, aged 3½ years, was admitted to the clinic June 27, 1912. He had complained of hoarseness with whispering voice dating back eighteen months. He had frequent attacks of dyspnea and at all times suffered from difficult respiration. His health was otherwise good. No specific history was obtainable. Examination of the larynx revealed multiple papillomas on both vocal cords and extending from the anterior commissure to the arytenoids. The color was that of the mucous membrane. July 11, fulguration was applied by the use of the Jackson speculum under chloroform anesthesia. Repeated applications of the fulgurating spark were made, July 18, August 1 and 15, and September 5 and 12. After each of these fulgurations the larynx would remain clear of laryngeal warts for a short space when they would recur. On the whole, the larynx showed some improvement up to the time of the last fulguration, September 12. At this time it was decided to make a severe test of the fulgurating spark, as it was necessary for the child to be removed to a different locality where he would not have opportunity of treatment or observation. Following this seance there was marked laryngeal reaction and labored breathing, continuing for five days. As the reaction was so severe it was determined to do a tracheotomy, which was performed, September 17. The next attempt at fulguration was made October 24, but as the patient took the anesthetic badly the spark was not applied. Subsequent to this, a number of fulgurations were given at varying intervals, it being easier of accomplishment after the tracheotomy-tube was in place. On the night of January 20, about 4 a. m., the child pulled out the tracheotomy-tube and died from asphyxia before the house surgeon could reach the ward. The nurse made an unsuccessful attempt to reinsert the tube.

Case 4.—E. F., a girl, aged 3 years, came to the clinic July 11, 1912, with symptoms of whispering voice and difficult breathing since birth. Her health had otherwise been always good. There was no history of either tuberculosis or syphilis. Examination of the larynx revealed multiple papillomas. Fulguration was first applied July 12, and there was immediate improvement in the voice. It was again applied July 18 and August 1 and 15, when she returned home and came to the hospital for treatment. September 1 she developed a diffuse bronchitis and was brought to the hospital; she recovered. September 28 she was fulgurated, following which there was some edema. In October she developed diphtheria in the ward and an immediate dose of 10,000 units of antitoxin was administered. She was carried to the infectious hospital where intubation was done, but died a few days later of pneumonia.

Case 5.—A history of this case has been mislaid, so that the report is made from memory. The patient was a little girl about 3 years old, who complained of hoarseness for two years. She was brought to the clinic where in addition to tonsils and adenoids the presence of laryngeal papilloma was discovered. Under local anesthesia fulguration was applied at varying intervals for three times, after each of which the larynx cleared up and the voice became better. There was no history of tuberculosis or syphilis. The child was well nourished and thick-necked. There was a long period following the last intubation in which there was no recurrence of the papillomatous growths. Just as hope was being raised that we had succeeded at last in overcoming the papilloma, the child developed measles and was taken to the Willard-Parker Hospital, where she recovered from her measles without any recurrence of the growths. Since the dismissal from the hospital no subsequent history has been obtainable.

44 West Forty-Ninth Street.

ABSTRACT OF DISCUSSION

Dr. Robert Levy, Denver: It is interesting to know that Dr. Smith has recommended in his paper a return to the thought expressed a great many years ago concerning the value of treatment by tracheotomy and waiting for the spontaneous disappearance of these growths. They have a certain life history and tend to disappear spontaneously, and so when we do a tracheotomy we put the larynx at rest and wait until this occurs. In a paper read a good many years ago I related a case that, to my mind, proved this and so up to a very recent time I have held that view and treated my patients accordingly. As a matter of fact, however, I think the time is coming, or has come, when we most modify our views somewhat. The reason, I believe, for the recurrence of these papillomas with such marked rapidity after they have been removed is that they were not removed thoroughly by our older methods, and this is particularly forced on one by the reading of the last article of Albrecht, in which he reports nine cases, some of which had been operated on by the ordinary way, by direct endoscopy, with constant recurrence, after which they were operated on by the suspension method. It was noticeable that the patients got well quickly and remained well. It may be that in all these cases the time had come for these growths to disappear, but the fact remains that no recurrence took place after they had been removed by the suspension method, while after their removal by the older method they did return rapidly. Of course, the time is somewhat recent to state that as a fact on which to base our future conduct in these cases. We can, however, by this means remove these growths very thoroughly. I have a case at present that proves Dr. Smith's infection theory; a child eight months old had a small papilloma in the anterior commissure; under direct suspension this was removed. I thought it a particularly easy case and one that would remain well but the growth returned with increased activity.

Dr. Samuel Iglauer, Cincinnati: Dr. Smith brought out most of the methods of treatment. In the series of cases that Dr. Levy referred to, I think the electrocautery was used after the removal of the papillomas. The removal of the papilloma by the suspension method, then cauterization, and perhaps prophylactic intubation to prevent edema would be good treatment. I now have two cases under treatment in which, through the kindness of Dr. Ransohoff, I have been able to employ radium. In one case, in an infant, the radium tubes were applied on the outside of the neck for several hours. A slight burn occurred on the skin but the papilloma did not disappear. In the second case I put the radium inside the larynx three times, with better results, and I think perhaps if Dr. Smith were to apply the radium for longer periods he might get better results. In my case it was applied five or six hours with no bad effects. The first time I tried radium I had some trouble in keeping the capsule in the larynx and I hit on this method; I put the capsule in a rubber tube slit on the side, like a drainage tube, with a string tied to it. The V-shaped cuts in the rubber tube acted like flanges to retain it in position. It held so well that on one occasion I had some trouble in removing it.

What is Sleep?—That is a nice problem for us to tackle. A French author said of life what we may say of sleep; it does not define itself, it simply manifests itself.—H. Crichton Miller, *Medical Press and Circular.*

THE TREATMENT OF CHRONIC PYELITIS *

J. T. GERAGHTY, M.D.

BALTIMORE

It is surprising how slow we have been to appreciate the benefits to be derived from pelvic lavage for the treatment of chronic pyelitis. It is probable that much of our tardiness in adopting this extremely beneficial treatment is largely due to insufficient methods of diagnosis, so that we were not able to select with a sufficient degree of accuracy the cases most suitable for lavage.

The successful treatment of chronic pyelitis is largely dependent on accurate examination and diagnosis. While it has been denied that chronic pyelitis can exist without involvement of the parenchyma, clinical experience and examination of pathologic material prove that a pure pyelitis can occur. Most cases of pyelitis are secondary to an infection of the kidney parenchyma or part of a pyelonephritis. The cases of pyelitis which are only a part of a pyelonephritis will not be discussed in this paper. While it is probably true, in most instances, that a pyelitis is secondary to a previous infection of the parenchyma, in many cases this infection in the parenchyma entirely disappears, leaving the pelvis and ureter alone involved. The majority of kidney infections, nontuberculous, are undoubtedly secondary to some predisposing factor, such as stone, tumor, stricture or other mechanical obstruction, and the amelioration or cure of the infection in such cases is dependent on the removal of the predisposing cause. It is surprising how frequently even a severe infection of the kidney and pelvis will disappear when these factors have been remedied. The differentiation of simple pyelitis from pyelonephritis may be quite difficult, and is practically impossible except by the employment of functional estimation. In pyelonephritis the function will be decreased, while, if it is a pure pyelitis, no reduction in function will be observed. Of course, one cannot always exclude the presence of a slight area of pyelonephritis which may not be sufficient to reduce the function, while in occasional cases the function may be diminished as the result of a previous pyelonephritis which has healed, leaving the pelvis still involved. One such case probably of this type is reported below. The presence or absence of albumin in the catheterized specimens has only occasionally been of diagnostic value in our hands. Pyelography is useful also in showing us changes which have occurred in the pelvis as a result of the infection, and gives us information which may be of considerable value from the point of view of prognosis. In our experience, the organism causing the infection has very little influence on the prognosis.

TREATMENT

When it has been determined accurately that we are dealing with a simple pyelitis, renal lavage is instituted, and in these selected cases the results of treatment have been little short of brilliant. We employed various solutions, such as argyrol, protargol, liquor formaldehydi, nitrate, phenol (carbolic acid) and aluminum acetate, but at the present time we have come to depend largely on silver nitrate and liquor formaldehydi. Vaccines have proved of very doubtful value, although we have employed them extensively. Hexamethylenamin has also proved of questionable value as far as the renal infection is concerned. Its value at the kidney level, as Hinman has shown, is very slight. The cases in which the lavage has been employed have been divided into the following groups:

---

* From the Urological Department of the Johns Hopkins Hospital.

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

1. Those in which the catheterized specimen shows the presence of a fairly active infection with a normal function and in which the collargol shows very few changes in the pelvic outline. The prognosis in this type of case is very favorable. We begin with injections of from 5 to 10 c.c. of 0.5 per cent. silver nitrate, the tip of the catheter being rather low down in the ureter. It seems advisable to inject from low down as in the majority of cases there is present also a certain degree of ureteritis, as well as pyelitis. The strength of the injection is gradually increased until we have used as strong as 5 per cent. It does not seem advisable to begin to inject with a very strong solution, because the reaction may be rather severe. The tolerance of the individual and the degree of reaction should be tested out first with weaker solutions. The occurrence of a fairly good reaction, however, is not to be avoided, as in the majority of cases this reaction is necessary before the infection can be eliminated. The splendid results obtained can be seen from the histories of a few appended cases:

Case 1.—P. L. P., aged 43, was always healthy until November, 1912, when he was suddenly seized with chills and fever and soon afterward developed frequency and painful micturition. Since then he has had repeated attacks of chills and fever, the urine has been cloudy and the general health failing. Patient has lost 40 pounds during the last six months. Seen Jan. 19, 1913. Bladder urine was cloudy and contained pus and colon bacilli. Ureter catheterization showed a normal and equal function on each side, but from the right kidney the urine was cloudy and contained pus and colon bacilli. From the left kidney the urine was clear macroscopically and on microscopic examination showed no pus-cells or bacteria. Collargol injection showed the pelvis and ureter apparently normal.

Jan. 26, 1913, the right kidney was catheterized and 10 c.c. of 0.5 per cent. silver nitrate was introduced. Following this first injection there was a marked improvement in the bladder urine. Four days later he was again catheterized and 0.5 per cent. silver nitrate again injected. Following the second injection there was some reaction. Within a week the bladder urine became perfectly clear and negative for infection on microscopic examination. Patient has remained entirely well and there has been no recurrence of the infection.

Another case is of particular interest because there was present a double infection, a *Staphylococcus albus* and a colon bacillus.

Case 2.—S, aged 38, seen March, 1914, had an unimportant past history except that he had had numerous attacks of gonorrhea. In December, 1912, patient had a chill and an elevation of temperature ranging from 102 to 106 F. Some days later he developed pain in the left kidney region. This attack of chills and fever cleared up in about three weeks. Since then he has had numerous attacks of chills and fever, sometimes associated with aching pain in the left lower back, which does not radiate. The urine has been cloudy since the onset of his present trouble. Very little frequency is present, and practically no urinary symptoms. On examination, patient is a slender, healthy-looking man. The kidneys are both slightly descended but do not seem enlarged. The bladder urine is quite cloudy and on microscopic examination contains pus, bacilli and cocci. (Cultures show these organisms to be colon and *Staphylococcus albus*, respectively.) Catheterization of the kidneys showed the urine from each side to contain pus, bacilli and cocci. The function was equal and normal on each side. Roentgen examination of the kidney was negative, and pyelography showed both pelves and ureters practically normal.

March 27, 1914, 8 c.c. of 0.5 per cent. silver nitrate was injected into each kidney. No reaction followed. March 30, 2 per cent. silver nitrate was injected into each kidney and this was followed by a moderate amount of pain in each kidney, more marked on the right side. April 6, 6 c.c. 2 per cent. silver nitrate was injected into each kidney pelvis. There was no pain following this treatment. April 11, the urine from each kidney was still slightly turbid and on microscopic examination contained a fair number of leukocytes, some bacilli and no cocci. Six c.c. of 5 per cent. silver nitrate was injected into each kidney pelvis. The patient suffered from considerable pain following the treatment and was rather uncomfortable for several days. Within three days the urine became entirely clear and repeated examinations failed to show any presence of infection. Patient has remained well until the present date. It is of interest that the staphylococcus disappeared before the colon, the colon infection being dislodged only by the use of the strong silver-nitrate solution.

The following case is of interest because of the marked difference in function between the two sides, and the presence of a double infection in the right kidney and a coccus infection in the left.

Case 3.—O., aged 42, was seen April 3, 1914, with a history dating back seven months. The onset of symptoms was with sharp, sudden pain in the right side, fever, nausea and vomiting. Since this first acute attack the patient has had several less severe. Has dull pain at times in the right flank and back and some frequency of urination and urgency. Has noticed that the urine has been quite cloudy since the beginning of his illness. On examination, patient is a well-nourished man, the right kidney is not palpable but there is some tenderness on deep pressure. Leukocytes on admission, 16,000. Roentgen examination is negative, bladder urine cloudy, specific gravity 1.025, acid, no sugar, trace of albumin, microscopically numerous pus-cells, staphylococci and bacilli.

April 7, cystoscopic examination and catheterization of ureters. Bladder somewhat injected, trigon reddened. Catheterization of the ureters gave the following results, the urine being collected for one-half hour.

Right:	Left:
Urine cloudy.	Urine clear.
Phthalein appeared in 7 min.	Phthalein appeared in 6 min.
Excretion 2 per cent. plus.	Excretion 29 per cent.
Urea 0.02 per cent.	Urea 0.17 per cent.
Microscopically: pus-cells, staphylococci and bacilli.	Microscopically: no pus-cells, no bacilli but some staphylococci.

On account of the leakage it was impossible to get an accurate estimation of the function at this examination, but 29 per cent. was excreted by the left kidney, 2 per cent. was collected from the right and the leakage amounted to 14 per cent. Even adding the leakage to the excretion of the right kidney, it can be seen that the function is only half that of the left. A collargol showed the pelves normal. Pelvic lavage was begun, at first using 1:4,000 liquor formaldehydi, later 0.5 per cent. silver, and this was gradually increased to 2 per cent. April 30, the findings were as follows:

Right:	Left:
Urine macroscopically clear but on microscopic examination contains a few bacilli and—cocci and an occasional pus-cell. Amount 21 c.c.	The urine was macroscopically clear but still contained groups of cocci. Amount 53 c.c.
Phthalein 12 per cent.	Phthalein 30 per cent.
Urea 0.6 gm.	Urea 0.7 gm.

No leakage.

Patient received two subsequent treatments at weekly intervals, with 3 per cent. silver nitrate. The urine at the last examination was entirely negative microscopically, one month after the last treatment. The difference in function between these two sides, both in the beginning and at the end of treatment, indicates either that the function of the right kidney was reduced from a previous pyelonephritis which had been cleared up, or that we are dealing with the infantile type of kidney. The equal concentration on each side would rather indicate the infantile type.

Another case illustrating the value of the strong silver nitrate when weaker solutions had absolutely failed to eliminate it, is the following:

CASE 4.—G. R. M., aged 20, was seen July 14, 1913. About two months ago patient noticed that he began to have frequency of urination and considerable pain on emptying the bladder. His general health seems good; the bladder urine is cloudy microscopically, shows pus and diplococci, which on culture prove to be a variety of *Staphylococcus albus*. On ureteral catheterization, the urine from the left kidney was slightly cloudy and on microscopic examination contained pus-cells and numerous cocci. The urine from the right kidney was clear. A pyelogram of the right kidney and ureter seemed perfectly normal. Roentgenoscopy was negative for stone. Total function was normal and the function of the left kidney was normal and equal to that of the right, as determined by phenolsulphonephthalein. Pelvic lavage was instituted and patient received four lavages of 1:4,000 liquor formaldehydi at five-day intervals; then two lavages of 1 per cent. silver nitrate at intervals of a week. At the end of this time there was no change in the infection present. It was then decided to inject the kidney pelvis with 5 per cent. silver nitrate, and about 10 c.c. was employed. Following this, patient had a fairly severe pain in the kidney region for several hours. The next day the bladder urine was smoky and on microscopic examination contained a good many blood-cells and a few leukocytes, but no bacteria. On the fourth day following the employment of the 5 per cent. silver nitrate the bladder urine was absolutely clear, microscopically negative for cocci and pus-cells. Patient was kept under observation for several weeks, and during that time the urine remained perfectly normal. Six months later he reported that he had remained well up to that time and that the urine was perfectly clear and normal-looking.

It is of interest here that no result was obtained until the strong silver nitrate had been employed and a considerable reaction produced.

2. In long-standing pelvic infections, in which marked changes have occurred in the pelvic wall, as shown by pyelography, and in which one finds in the catheterized specimens very few leukocytes and only an occasional bacterium, the prognosis is not so favorable. The infection in these cases is of a low grade, usually quite deep in the pelvic wall, so that it is very difficult to eradicate it. Occasionally, in these cases, after a certain amount of treatment, the infection may apparently disappear, but it usually recurs again. These cases sometimes have slight exacerbations when one finds considerable pus and bacteria and at other times almost a perfectly negative urine, as far as the most careful microscopic examination can determine. One should be very careful about giving a good prognosis as far as eradication of infection is concerned, in this class of case.

3. In infections of the kidney pelvis, associated with a certain amount of pelvic dilatation and varying amounts of residual urine, pelvic lavage has also been of comparatively little value. The most unfavorable are those in which the condition is largely a bacteriuria. While it is possible in many cases by lavage to improve to some extent the character of the urine and decrease the severity of infection, the results of lavage have not been particularly gratifying so far as complete eradication of infection is concerned. In cases in which nephrectomy is contra-indicated, pelvic lavage should be tried because not infrequently, while it is impossible to entirely eradicate the infection, a great improvement in the condition may follow renal drainage and lavage. In these infections with mild hydronephrosis, silver nitrate seems to give less favorable results than solutions of formaldehyd, which we employ in strength from 1: 5,000 to 1: 2,000. Under such conditions, it is advisable to introduce a catheter into the pelvis of the kidney so as completely to empty the residual urine.

ABSTRACT OF DISCUSSION

DR. I. S. KOLL, Chicago: I heartily agree with Dr. Geraghty as to the indications for pelvic lavage, that is, as differentiating a pyelitis from a pyelonephritis. My experimental work, however, made me believe that as a pathologic entity we have no such thing as a pyelitis, because twenty-four hours after 1 c.c. of a twenty-four-hour colon-bacillus culture is injected into the ureter, the kidney, when examined histologically, will show a definite pyelonephritis, care having been taken not to traumatize the kidney or ureter. It certainly was a revelation to hear that any one was brave enough to inject silver nitrate in 5 per cent. solution into the ureter and pelvis of the kidney. I believe everything Dr. Geraghty says, but let us, for a moment, consider the rationale of the use of nitrate of silver. In 5 per cent. strength it is a powerful astringent and escharotic, and has a tendency to form a coagulation of the epithelial cells and prevent any penetration of the drug itself. It therefore has not much chance of doing good. The work that I did with liquor alumini acetatis five years ago showed that in chronic pyelitis cases there is a definite penetration of the bacteria into the tissues. How long has Dr. Geraghty followed his cases? What percentage has shown recurrences? When does he cease to use lavage of the kidney? I differentiate strongly between a clinical cure and a bacterial cure. I never stop lavaging in my cases until a catheterized specimen from the ureter of the infected side fails to give a culture of the organism, which in 98 per cent. of the cases is due to the colon bacillus. That is an all-important point, I believe, and I am sure that most of us have had recurrences time and again because we stopped our treatment before the bacteria disappeared. It is not difficult to get rid of the pus-cells, but the colon bacillus will remain there in pure culture for a much longer time.

DR. MARTIN KROTOSZYNER, San Francisco: I am glad to hear that Dr. Geraghty has used strong solutions of silver nitrate, because I have always held that weak solutions of 1:10,000 never have any beneficial effect. I have never gone as high as 5 per cent., but, as a rule, I start with 1:500 and go up to 1 per cent., and I admit that my assistants would look at me askance when I carried my injections up to 1:200 and even 1 per cent., but I am glad to see that at Johns Hopkins they do not stop until they reach 5 per cent. At what intervals does Dr. Geraghty use these injections? I want to take exception to one more statement. With Dr. Geraghty I believe in the teaching of Casper that the differential diagnosis of pyelitis and pyelonephritis can be made on the basis of the functional kidney tests. I have seen lately a case in which I was mistaken. I exposed the kidney in a case in which I had made the diagnosis of pyelonephritis from a very low kidney function on the affected side. When I opened the kidney I found it perfectly normal, with simply a dilated pelvis, showing the presence of a pyelitis. I will admit the kidney was interfered with in function by adhesions around the ureter, but the pathologic report on the pieces that were excised confirmed the preoperative diagnosis of pyelonephritis.

DR. LOUIS E. SCHMIDT, Chicago: I disagree, to a certain extent, with Dr. Geraghty. He makes rather a clinical diagnosis, and of course when we talk about cures we also depend on the clinical results. It would really be interesting to be able to demonstrate kidneys of this kind after death really to see what the exact changes have been, that is, if the patient has really passed through a distinct pyelitis. I do not believe that a pure and simple pyelitis exists. I have always been under the impression that there is at least a very mild degree of pyelonephritis present; hence that all this local treatment is, at least in the vast majority of instances, not followed by the best results. Of course, Dr. Geraghty divides his cases and states positively that there is one type, exceptionally common, which responds to this mode of treatment. I do not believe pyelography is necessary for the diagnosis of pyelitis. I object to the general use of this method of examination. I do not see what distinct information we can get, except possibly slight changes in the papillae, etc., but I do not believe a diagnosis can be made from that. If we do a ureteral catheterization and find that we have a slight enlargement of the pelvis, I think that will give us a certain amount of information, and naturally the ordinary urinary examinations that go with it are useful; but in cases of this kind I do not think that pyelography is absolutely essential in the diagnosis. As it is a question of formulating the exact conditions of when we should do pyelography, I would be glad to hear what Dr. Geraghty has to say about this method of examination in differentiating these conditions. When it comes to the diagnosis of pyelitis, I lean more on the clinical course than on a lot of these so-called more exact methods. When we come to the treatment a good many depend on internal medication. Of course, there are objections to that, but I am still skeptical as to lavage. I have gone through that for a good many years. It is true that I have not treated all cases indiscriminately, but I have still to see any practical results from lavage of the pelvis of the kidney.

Dr. W. E. Stevens, San Francisco: Does Dr. Geraghty use vaccines in the treatment of any of these forms of pyelitis?

Dr. John T. Geraghty, Baltimore: A pyelitis cannot be considered cured until repeated examinations have shown the urine to be free from infection and bacteriologically sterile. In our series of cases we have only considered as cured those in whom this result was obtained. Pyelography has proved of considerable value in differentiating those with marked changes in the pelvic wall from the type in which these changes have not occurred, and the knowledge obtained in this way has been useful from the point of view of prognosis. I can see no objection to using pyelography in these cases, particularly when it is done carefully and the gravity method alone is employed. Since employing the gravity method of injecting the pelvis, we have had no ill results. We used vaccines some years ago quite extensively in the treatment of pelvic infections, but were never able to see any specific benefit which could be ascribed to the vaccines alone. At present we employ them but seldom.

THE RELATION OF UREA TO THE TOTAL NITROGEN OF THE BLOOD IN HEPATIC DISEASE *

CLIFFORD B. FARR, M.D.
AND
EDWARD B. KRUMBHAAR, M.D.
PHILADELPHIA

The object of this investigation was to test by the new and dependable method of Folin the assertion of various French investigators that in cirrhosis and other diseases of the liver the percentage of urea in the blood is diminished.

Folin's method had given one[1] of us excellent results in the study of the blood of nephritis, and although we were skeptical about obtaining definite evidence of changes in the blood in hepatic disease, the accuracy of Folin's method seemed to offer the best means of reaching a conclusion. Our scepticism may be explained as due in part to our belief that even in so extensive a disease of the liver as cirrhosis, enough normal liver parenchyma remains—the so-called "factor of safety"—to carry on the normal function, and also to the well-known fact that in all diseases of the liver of the cirrhotic type, regenerative proliferation of hepatic parenchyma is more or less constantly present. With the wide margin of safety offered by these two factors it appeared highly improbable that a noteworthy diminution in urea formation would be found.

UREA AND TOTAL NITROGEN OF BLOOD IN HEPATIC DISEASE

Diagnosis	Total Nitrogen mg.	Urea mg.	Remarks
I. CIRRHOSIS			
1. Portal cirrhosis	25.5	12.4	
2. Portal cirrhosis	34.2	17.7	
3. Portal cirrhosis; splenomegaly	28.9	14.4	Occasionally albumin and casts
4. Portal cirrhosis	33.8	16.8	
5. Portal cirrhosis	23.5	12.7	
6. Portal cirrhosis	22.2	12.7	
7. Portal cirrhosis	40.9	20.0	Nephritis
8. Hypertrophic cirrhosis*.	30.3	15.3	Albumin and casts
9. Hypertrophic cirrhosis..	45.9	24.1	Nephritis
II. CANCER AND JAUNDICE			
10. (1) Carcinoma of liver (2) Carcinoma of liver†	69.5 35.0	30.0 13.4	Occasionally albumin
11. Carcinoma of liver, jaundice	72.7	high‡	Albumin and casts
12. Catarrhal jaundice	35.2	14.3	
III. CHRONIC PASSIVE CONGESTION OF LIVER			
13. Passive congestion; myocarditis	24.7	12.2	Occasionally albumin
14. Passive congestion; chronic endocarditis.	31.3	16.6	Albumin and casts
15. Passive congestion; cardiorenal	23.9	11.6	Albumin and casts
16. Passive congestion; chronic endocarditis.	22.7	11.0	
17. Passive congestion; syphilitic aortitis ..	38.2	22.5	Albumin and casts
18. Passive congestion; chronic endocarditis..	51.2	33.9	
IV. CONTROLS			
19. Typhoid fever (suspected cirrhosis)	23.7	11.2	Occasionally albumin
20. Nephritis (?)	24.7	10.4	
21. Tuberculous hip disease	34.1	19.3	
22. Convalescent typhoid ..	23.9	12.2	
23. Normal	30.1	14.8	

* Reported previously by Farr and Austin, Case 56.
† Second test performed two weeks later.
‡ Too high to be read with dilution employed.

The earlier observations based on the older methods of study are as follows: Morel and Mouriquand,[2] using the Pflüger-Braunstein method, found that whereas in nephritis the percentage of urea in the blood varied from 64 to 77 per cent., in hepatic disease it ranged from 33 to 50 per cent.

---

* From the John Herr Musser Department of Research Medicine, University of Pennsylvania.

[2] Morel, A., and Mouriquand, G.: Urémie et azotémie; considerations sur la signification de la retention des corps azotés dans le sang des cirrhotiques, Bull. et mém. Soc. méd. d. hôp. de Paris, 1913, xxxv, 266.

Courmont, Boulud, Savy and Blanc-Perducet[3] studied the urea percentage in the blood by Boulud's method. Twenty-two cases, mostly nephritics, gave an average of 80 per cent., whereas the one cirrhotic studied gave 42 per cent.

Brodin[4] also found that the urea percentage was decreased in hepatic disease and the "non-ureic" nitrogen correspondingly augmented. Finally, Chauffard[5] called attention to the fact that the estimation of the urea percentage might be inaccurate on account of changes due to diet or an accompanying nephritis, and suggested, as a better criterion, the estimation of the "residual or non-ureic" nitrogen. By this was meant the determination of the difference, in milligrams per hundred c.c., between the urea and the total non-protein nitrogen of the blood.

Our results are shown in the accompanying table, and present the average of duplicate estimations made according to the method of Folin and Denis.[6] The figures indicate in milligrams the respective amounts of urea and total nitrogen per hundred c.c. of blood. The percentage of urea and the difference between total nitrogen and urea (Chauffard) were calculated in each instance, but as these figures did not prove to be of value, we have, for the sake of brevity, omitted them.

SUMMARY

In the various forms of cirrhosis, as presented in the first portion of the table, the total nitrogen was markedly increased only in those accompanied by definite nephritis. The moderate increase seen in rare instances may have been due to slight renal involvement not shown by our clinical tests. The percentage of urea was in each case approximately 50 per cent., which we regard as normal.

The second group of three cases, in each of which severe functional disturbances might have been expected, did in fact show changes suggestive of hepatic insufficiency. The percentage of urea ranged from 38 to 43 and the difference from 21 to 40. Similar results were occasionally found in cases of eclampsia, reported elsewhere,[7] in which impaired liver function was presumably present.

Our third group consisted entirely of cases of chronic passive congestion of the liver secondary to heart disease. In none, according to the criteria mentioned, did we find any suggestion of hepatic insufficiency. The urea percentage ranged from 47 to 66.

In the fourth, or control group, the urea percentage ranged from 42 to 57, essentially normal figures.

In conclusion it may be stated that our observations offer little or no support of the view that in destructive disease or severe functional derangement of the liver the percentage of urea in the blood is reduced. In the group of diseases studied our figures are close to the normal. In cirrhosis of the liver, a disease in which functional tests would be of the greatest value the determination of blood urea offers no information of use in diagnosis.

LATENT ATYPICAL MALARIA COMPLICATING THE PUERPERIUM

M. J. SEIFERT, M.D.
CHICAGO

Manaberg claims that pregnancy constitutes no protection against malarial infections, notwithstanding the statements of the older observers to the contrary. In a gravid woman, malarial infection often takes on a severe form. The influences making for anemia in cases of even slight infections are more potent in pregnant women than in others, as abortions frequently occur.

Weatherly reported that in India, 46 per cent. of his cases aborted, while in England the frequency amounts to only 3.56 per cent.

Pellereau reports the same conditions in Mauritius. The abortion does not require a fever nor a paroxysm for its production, the fetus usually being dead before abortion occurs.

Weatherly also finds sterility among women in India of common occurrence, which he attributes to malaria.

According to Chevers the act of parturition often operates as an exciting cause in an outbreak of malaria, during which lochial and lacteal secretions cease. The same was reported by Parker of New York. He had only one death among forty-seven cases. Repeated blood examinations would naturally be very desirable in similar cases, as the possibility of septic infection is very great. Since the parasite of masked malaria is not always found in the peripheral blood, special emphasis is laid on the repetition of blood-tests in obscure cases. The frequency of masked malaria varies inversely with the care and thoroughness employed in diagnosis, and diagnosis must be based on microscopic findings and therapeutic tests, as symptoms *per se* are only confusing.

The case about to be described is one of latent atypical malaria complicating the puerperium in a patient afflicted with chronic nephritis of long standing. This report is of more than passing interest to the general practitioner and especially to the obstetrician for clinical study, as no like case has been found in the literature.

REPORT OF CASE

Mrs. X., aged 25, American, lived in Illinois all her life. When 2 years old she had a severe attack of "summer complaint." Puberty at 12 years was uneventful so far as the establishing of normal menstruation was concerned, but the patient was ill four weeks at that time as the result of a fall on her head while at turning school. At 15 years the patient became anemic, which condition persisted to the age of 18 when she was unable to walk for one month on account of dropsy. During this period she was afflicted with frequent fainting spells.

June 20, 1900, at the age of 20, the patient was married. May 9, 1901, aged 21, she was confined and delivered of a fine healthy boy weighing about 10 pounds. On the sixth day after labor she had chills and fever which at that time I attributed to a probable infection as there was no trained nurse in attendance. There were no manifestations of puerperal sepsis, no pelvic symptoms, no offensive lochia and no stitch infection. The perineal lacerations were bilateral though not extensive; the cervix sustained slight tears on both sides. Unfortunately, no clinical record could be made of this sickness which lasted about three weeks. The treatment was not antimalarial, but tonic and supportive—entirely symptomatic. The patient made an uneventful recovery and, to use her own expression, "enjoyed better health than ever before in all my life." This state of good health lasted until her next pregnancy. Feb. 22, 1905, aged 25, at 4:15 a. m., patient gave birth to a 12-pound boy in St. Mary of Nazareth Hospital, Chicago. There were extensive lacerations of the cervix uteri and of the perineum and more than ordinary hemorrhages. The latter caused three fainting spells. The labor came on so suddenly that I had no time to summon an intern. No vaginal examinations were made as there were no indications of any pathologic conditions, and, besides, there was no time for ascertaining details between the time of her admission, late in the evening of February 21, to the time of the spontaneous labor, 4:15 a. m. February 22. As persistent uterine inertia followed, the placenta was delivered artificially. This caused a fourth fainting spell. The patient was allowed a brief respite, until 8:15 a. m. when I repaired the cervical and perineal lacerations, using only a few whiffs of an anesthetic as she insisted on exercising her will power. A fifth fainting spell occurred in the operating-room after the completion of the suturing. During the night the temperature rose to 100 F. and the pulse to 120, but both were normal the next morning. Every function was normal with the exception of the pulse, which ranged from 90 to 100 and above—in fact the pulse was often above 100. Owing to the nervousness of the patient and the absence of any discoverable disease other than chronic nephritis with its usual comcomitants, no unusual significance was attached to this feature of the case, especially since the pulse was otherwise normal.

February 28 the left breast became indurated and painful and the patient had slight chills and complained of nausea. At 6 a. m. the temperature rose to $102\frac{9}{10}$ F. and the pulse to 104. The breast was massaged and boric-acid fomentations and breast pump were applied. The nipple being fissured, was treated with glycerite of tannic acid. Enemata and sponge baths were given for eliminative and antipyretic purposes. Then there ensued the following play of pulse and temperature:

Date	Time	Pulse	Temperature F.
3/1	4:00 a. m.	120	103
	4:30 p. m.	128	$104\frac{2}{10}$
	8:45 p. m.	90	102
3/2	12:30 a. m.	140	104
	3:30 a. m.	120	103
	5:30 a. m.	120	$100\frac{2}{10}$
	2:00 p. m.	108	$99\frac{9}{10}$
	6:00 p. m.	100	99

Pulse then became normal. There were no symptoms of any pelvic infection, hence puerperal septicemia was excluded. As the breast was the only offending organ that was discovered at that time, I held it accountable for the vagaries of the pulse and temperature and, naturally, when these dropped to normal, simultaneously with the cessation of all untoward breast symptoms, I thought the difficulty was overcome. Urinalysis showed specific gravity 1.032; 4 per cent. albumin by volume; trace of sugar; some hyalin and a few granular casts.

The next day I was made uneasy by the following clinical record:

Date	Time	Pulse	Temperature F.
3/3	3:00 p. m.	124	100
	6:00 p. m.	128	102
	10:15 p. m.	130	104

The record remained about as above until it became more serious, namely:

Date	Time	Pulse	Temperature F.
3/4	3:00 a. m.	128	105
	8:45 a. m.	130	$105\frac{2}{10}$
	11:00 a. m.	120	104

The condition becoming alarming, I requested consultation. After an exhaustive examination consultant assured me that there was not one sign of any pelvic infection, and in his subsequent daily visits found no reason to alter his opinion.

In spite of finding no pathologic lesions of any kind, there was no improvement in the pulse-temperature wave which rose to 140 and $106\frac{8}{10}$ and never dropped below 110 and 101, respectively. There was not even the slightest periodicity in these records. Feeling that we were making no progress and that the patient was losing ground daily, a second consultant was sought. A careful study of the case, course, examinations made and treatment given, revealed the fact that malaria was about the only disease not thought of. While the clinical record did not support any malarial theory, yet a blood examination was advised and ordered and large numbers of the parasites of the tertian variety were found.

Specific antimalarial treatment (quinin bisulphate 2 grains followed by a cup of hot water every two hours) produced good results in twenty-four hours. In forty-eight hours convalescence was established and recovery was gradual and positive. No other untoward symptoms appeared, excepting cinchonism which was overcome by adding sodium bromid, 5 grains to each dose of quinin.

After all symptoms subsided, the patient normal in every respect and ready to be discharged, she complained of slight tenderness in the pelvis. Some lochial discharges appeared March 21, 1905, which, on microscopic examination, were found to contain gonococci. The husband admitted to consultant and to me that he had been afflicted with gonorrhea.

SUMMARY

The patient never lived in a strictly malarial locality. The symptoms were not at all typical of malaria. The patient never had an attack of malaria until after labor. The anemia that occurred between the ages of 15 and 18 might have been the result of malarial intoxication (in latent form). The occurrence of irregular chills and fever in two consecutive confinements and never at any other time, with no pelvic involvement and with positive microscopic findings in the second, merits attention. The late gonorrheal complications after the second puerperium about thirty days after labor and long after other conditions were normal, was an extraordinary experience. Every case of fever following labor is not puerperal sepsis.

Finally the most important part of this paper is the lesson to be learned from a lack of thoroughness in diagnosis. I offer no apology, as there was an acute exacerbation of nephritis engrafted on a chronic nephritis of long standing, together with acute mammitis and the atypical malarial manifestations, to say nothing of the late gonorrheal infection, all of which formed a symptom-complex so confusing and so perplexing that it was indeed not easy nor yet hardly reasonable to expect to decipher such symptoms as would make for a diagnosis of malaria.

I make a strong plea for exhaustive methods of diagnosis as a routine practice, and the lesson I would take to heart if still engaged in an obstetric practice, would be to take nothing for granted and to examine all unusual cases exhaustively, carefully studying clinical data, and especially to go the limit in the laboratory methods of diagnosis.

Yellow Fever Commission.—The reports of the Yellow Fever Commission of West Africa have been issued and the following conclusions are drawn: 1. Yellow fever has occurred from time to time since 1778 in various parts of the British West African colonies. 2. There is no evidence to show that the infection in each outbreak has been introduced from outside Africa. 3. The mild nature of the attack in certain cases makes identification a matter of great difficulty. It is therefore essential that in future all cases of fever should be carefully observed and classified in order that, so far as possible, such mild cases may not pass unrecognized. 4. The attention of all workers at this subject should be specially directed to the discovery of a clinical test for yellow fever.

A METHOD OF DIMINISHING HEMORRHAGE AFTER SUPRAPUBIC PROSTATECTOMY *

EDWARD L. KEYES, JR., M.D.
NEW YORK

Discussion of the amount of bleeding that follows suprapubic prostatectomy is not likely to profit us anything. I have at various times been convinced that a certain method of removing the prostate markedly diminished the hemorrhage, but no sooner was this opinion in the way of becoming a certainty than it was rudely shattered. My personal preference is to enucleate the prostate by the so-called intra-urethral method. To avoid the hemorrhage I have tried packing, and making the incision through the mucous membrane by means of a Bottini instrument introduced into the urethra. This did not much diminish the hemorrhage, and it did have the inconvenience of leaving one of the four or five patients on whom I operated in this way with partial incontinence of urine. I next tried to suture the neck of the bladder in one case; the patient died of hemorrhage. Since then I have employed the following technic in ten cases:

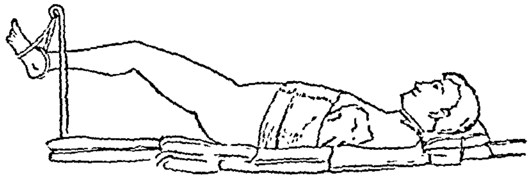

Fig. 1.—Position of patient in author's operation with legs supported on leg-rests and with hips at an angle of about 45 degrees.

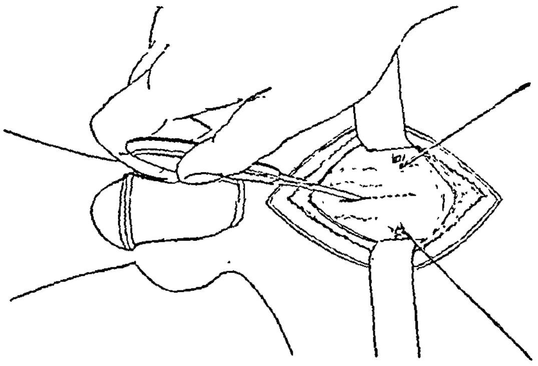

Fig. 2.—The bladder exposed through a suprapubic incision, suspended by two skin hooks; incision between the hooks.

The patient is put on the operating table in the dorsal position but with his legs supported on leg-rests so that the hips are flexed at an angle of about 45 degrees (Fig. 1). The hypogastrium, the genitals, the perineum and the adjoining portions of the thighs are then cleaned in the usual manner, and this wide field is left uncovered by towels.

The bladder is exposed through a suprapubic incision, suspended by two skin hooks, and incised between these (Fig. 2). The prostate is then rapidly enucleated between two fingers in the rectum and two in the bladder. Then a grooved staff is inserted into the urethra and a long Peaslee or Reverdin needle, threaded with a piece of catgut about 18 inches long, is plunged into the groove of the staff through the perineum (Fig. 3) quite in the same way as one uses a bistoury in doing a rapid perineal section.

The needle is passed along the grooved staff until it can be felt in the bladder by a finger in the suprapubic opening. The staff is then withdrawn and two Walker suprapubic bladder retractors[1] are introduced. These, by making lateral traction on the bladder, elevate the torn edges of the bladder neck like a veil and make it plainly palpable to the examining finger.

The needle, carrying the catgut, is inserted through the edge of this veil, just deep enough to get a good hold, at a lateral angle (about 7 o'clock) (Fig. 4). Then by depressing the handle of the needle its eye is brought up into the suprapubic wound so that the catgut can be disengaged (Fig. 5). This accomplished, the needle is withdrawn from the puncture in the bladder neck and reintroduced at a corresponding point on the opposite side, again threaded with the catgut, allowing plenty of slack (Fig. 6), then rapidly withdrawn through the perineum. The threading and unthreading of the needle is expedited by removing the corresponding Walker retractors immediately after the puncture of the bladder neck on each side. If an indwelling catheter is to be employed, it must be inserted now.

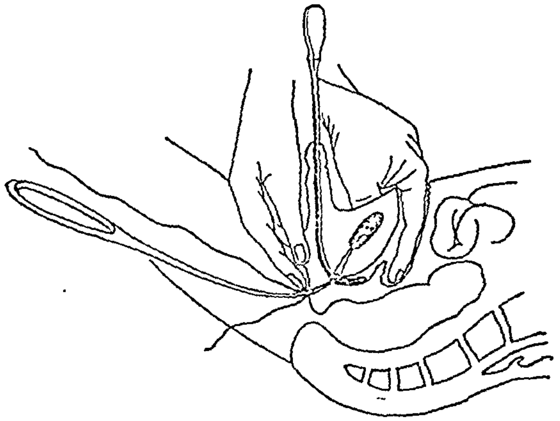

Fig. 3.—Peaslee or Reverdin needle threaded with catgut inserted through perineum along grooved staff.

After the needle has been withdrawn we have in our hands the two ends of a suture entering through a single puncture in the perineum, passing through the deep urethra and to the bladder neck and catching the lower segment of this at its two angles (Fig. 7). Traction on the ends of the loop pulls the bladder neck down

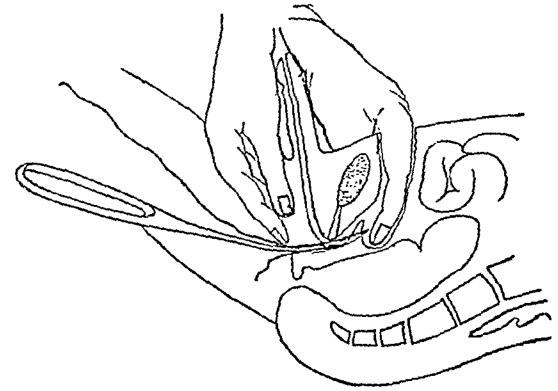

Fig. 4.—Showing method of inserting needle through the torn edges of the bladder neck, made tense by retractors.

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[1] After becoming accustomed to the technic of the operation one may dispense with this retraction.

into the urethra. It thus controls hemorrhage, chiefly, I fancy, by putting the bladder neck on tension. The ends of the suture are then tied about a short rubber tube laid against the perineum, after the bladder neck has been pulled down very firmly (Fig. 8).

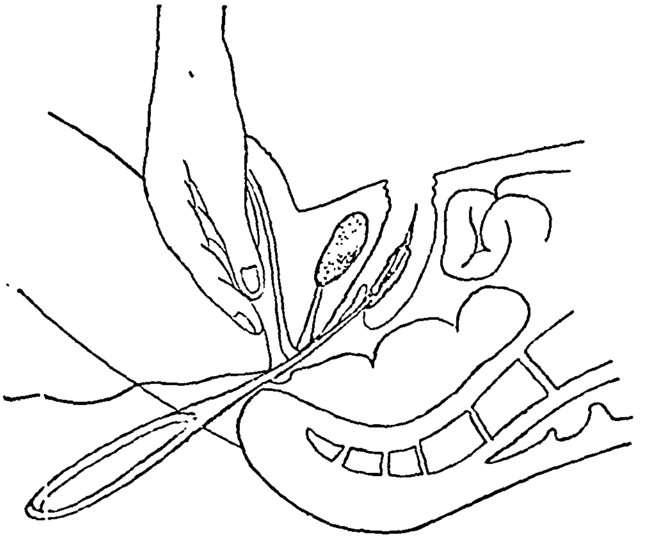

Fig. 5.—The eye of a needle is brought up into the suprapubic wound by depressing the handle so that the catgut can be disengaged. The needle is then withdrawn.

Drainage is provided by the usual suprapubic tube or by a catheter in the urethra, and a tube in the suprapubic wound, according to the fancy of the operator. I am using a rather small suprapubic tube in these cases, but do not care to do away with it altogether with the memory fresh in my mind of the gentleman who so recently advocated complete suture of the bladder after suprapubic prostectomy and is reported to have returned home only to find that the heralded improvement had been discarded during his absence. The suture is divided and withdrawn from eighteen to twenty-four hours later. With this technic the immediate hemorrhage has been promptly checked, and the ultimate bleeding has been much less than it would otherwise have been. I have not seen any fistula or inflammatory complications along the track of the suture in the perineum.

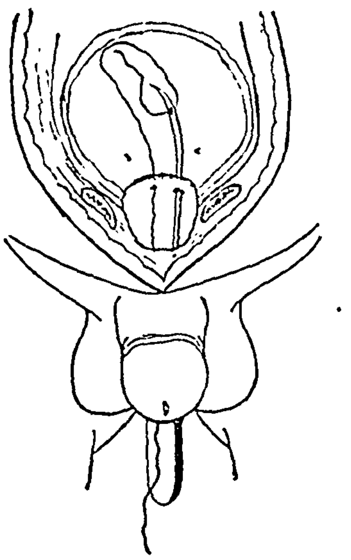

Fig. 6.—The needle reintroduced at corresponding point on the opposite side, again threaded with catgut and then withdrawn through the perineum.

109 East Thirty-Fourth Street.

ABSTRACT OF DISCUSSION

Dr. Francis R. Hagner, Washington: A little bag that I have devised does practically the same thing as Dr. Keyes' ingenious process. This bag has a string attached to one end, at the other a hollow rubber tube. A long curved sound is passed through the urethra, the tip of the rubber tube is pulled over the end of the sound, and the sound withdrawn, bringing with it the tube. The bag is now lying against the neck of the bladder, with a tube coming out through the urethra and a string through the suprapubic opening. The bag is inflated with a large syringe. The finger should be passed around the bag to see that the torn mucous membrane falls back into the cavity from which the prostate was removed. The bag is allowed to remain for from twenty-four to forty-eight hours, but is deflated at the end of twelve hours. To make the bag collapse perfectly it is necessary to use suction with the syringe. To remove it, the tube is cleansed as thoroughly as possible with soap and water and mercuric chlorid, and traction is made on the string while the tube is fed into the urethra. We have used this bag in eleven cases. There is practically no bleeding. If you wash out the bladder there will be just the slightest staining of the fluid. In one case the bag was not big enough. The first bag I had made was 11½ cm. in circumference. It will probably be necessary to have larger sizes, say, 13½ and 15½ cm. In the case in which bleeding occurred the internal sphincter did not contract down as it should. I remarked on it at the time. It is a very simple device. The patient is not uncomfortable; and the bag is removed without pain.

Dr. Charles E. Barnett, Fort Wayne: If the drainage were taken out within from twelve to twenty-four hours, there would be no danger; but if the drainage is kept *in situ* for a longer period than that it appears to me that there would be more danger from the means used to control hemorrhage than there would be had we not used any method of control, for should the drainage tube from its trauma loosen up a clot that had formed in the mouth of a vein there would be great danger from thrombi and emboli. The majority of men who are operating to-day pay no attention, particularly, to hemorrhage, unless the case is hemophiliac. The hemorrhage controls itself.

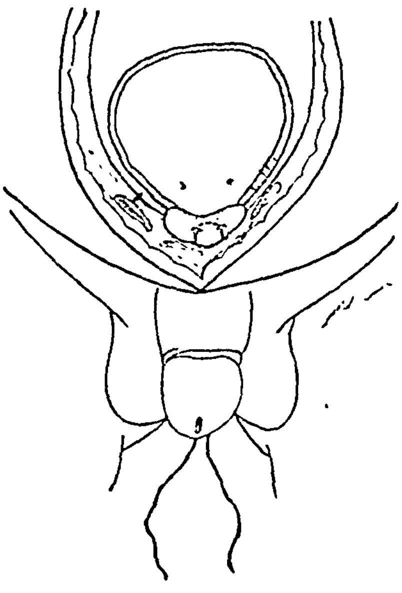

Fig. 7.—Showing the two ends of the suture entering through a single puncture of the perineum, passing through the deep urethra and to the bladder neck and catching the lower segment of the latter at its two angles. The traction on the ends of the loop pulls the bladder down into the urethra.

Dr. E. L. Keyes, Jr., New York: I respect Dr. Barnett's opinion, which is, however, contrary to my own. I consider that hemorrhage is dangerous in many cases; in certain cases, however, it is not dangerous. If we are to employ any technic for the control of hemorrhage, it is better for the sake of our own expertness and rapidity of action that we employ that technic in all cases. Neither in delay at the time of operation nor in complications have I felt that the technic I employ adds anything to the patient's danger.

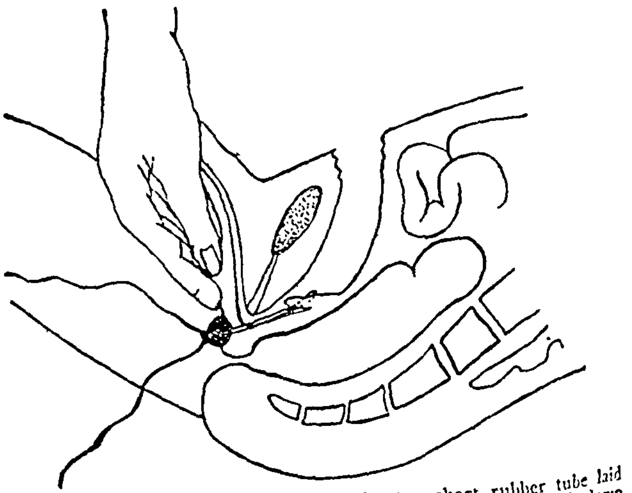

Fig. 8.—The ends of the suture tied about a short rubber tube laid against the perineum after the bladder neck has been pulled down firmly as shown in Figure 7.

THE TREATMENT OF HYDROCELE

WITH SPECIAL REFERENCE TO PHENOL INJECTIONS *

ROBERT H. HERBST, M.D.
Instructor in Genito-Urinary Surgery, Rush Medical College
CHICAGO

Although a serous effusion into the sac of the tunica vaginalis occurs as an independent malady, in the vast majority of cases we find an underlying pathologic condition of one or more of the anatomic structures found in the scrotum. Hydrocele frequently accompanies the acute infections of the epididymis and testicle, but is more commonly found complicating the chronic infections of these organs, such as tuberculosis and syphilis. As a rule when the hydrocele is secondary to a tuberculosis of the epididymis, the tuberculous process is far advanced, having traveled down the cord, involving both the prostate and vesicles. In such cases it is my belief that an open operation is contra-indicated. Again, in those cases due to syphilis of the testicle, the removal or stitching of the sac behind the testicle is entirely unnecessary.

When the sac of the tunica vaginalis is well filled with fluid, it is often very difficult to palpate the contents of the scrotum. Therefore if we consider the conditions underlying hydrocele, namely, acute infections of the epididymis, such as gonococcus and pus infection (rarely colon), tuberculosis, neoplasms of both testicle and epididymis, syphilis of the testicle, also hydrocele resulting from traumatism of these organs, it is obvious that a preliminary tapping and evacuation of the sac is always indicated before choosing between the open operation and the injection of phenol (carbolic acid).

If preliminary tapping is practiced, it will prevent the too common error of opening the sac and finding an advanced tuberculous process behind the fluid. The same holds true in cases of syphilis of the testicle, in which, in all probability, there would be recovery with antisyphilitic treatment.

If I may be allowed to eliminate those effusions into the sac of the tunica vaginalis which accompany the acute infections of the epididymis and which usually disappear as the acute process subsides, it is my contention that the results following tapping and injection of phenol are as good as are seen following any of the open operations, provided the sac be thoroughly washed with sterile water after the serum has been evacuated and before the phenol is injected.

The common recurrences following the old method of injecting phenol without the preliminary washing out of the sac were due to the fact that the sac wall was covered with serum, which coagulated the phenol and did not allow the acid to come into contact with the sac wall. To obviate further such a contingency it has been my practice to test the return fluid for albumin and to continue the washing of the sac until the fluid fails to give a reaction to nitric acid. Then from 10 to 12 c.c. of 95 per cent. phenol are injected, the scrotum at the same time being manipulated so as to bring the acid into contact with all parts of the sac; then the excess is allowed to flow out, after which about 15 c.c. of alcohol are injected.

The injection of sterile water into the sac serves the double purpose of cleansing the sac wall and prevents the not infrequent accident of injecting the phenol into the tissues of the scrotum. During the emptying of a well-filled tunica vaginalis the receding sac wall is likely to draw away from the end of the cannula without the knowledge of the operator. If this does occur and the water is injected, it does not return, but remains in the tissues of the scrotum, which appear edematous. Under such circumstances the sac must be allowed again to fill with serum before an attempt is made to inject the phenol. The use of the Belfield hydrocele trochar and cannula, however, will practically always prevent this accident because it fixes the sac, by passing through two of its walls. The refilling of the sac which is commonly seen during the first twenty-four hours after the injection is due to the reaction of the tissue to the phenol and disappears spontaneously within a few days.

For the number of years that I have been practicing this method of washing the sac before injection I have observed very few recurrences. These few were in most instances due to a slight reaccumulation of serum, during the first week or two after the injection, and after a simple evacuation the cure was permanent.

In cases of chronic pachyvaginalitis in which the sac wall has become greatly thickened, excision is preferable to either eversion or injection. As is sometimes supposed, injection of phenol is not followed by atrophy of the testicle, although it may rarely produce a peritesticular sclerosis.

As for the objections that might be advanced relative to the toxic effect of the phenol, I would say that neither in my own experience nor in the literature have such results obtained.

CONCLUSIONS

1. Considering the underlying pathology of many cases of hydrocele, it is my belief that open operation for the relief of this condition is usually unnecessary and frequently contra-indicated.

2. When the sac is thoroughly washed with sterile water before the phenol is injected, recurrences are very rare.

32 North State Street.

ABSTRACT OF DISCUSSION

Dr. A. A. Martin, New Zealand: Will Dr. Herbst say whether there is any pain after using this method?

Dr. V. D. Lespinasse, Chicago: I have often used phenol (carbolic acid). One of my early experiences was in a case of sloughing of the scrotum from carbolic acid, due to improper technic. That gave the method a sort of black eye in my own opinion. Later on I used the device of Dr. B. Einasson and somewhat simultaneously Dr. Belfield brought out his cannula. Since then I have used that with good results. Lately, instead of using phenol, after making the puncture and as the fluid is running out, I thread some chromic catgut into the sac. The catgut technic causes a little more pain the next day, but there is no chance of sloughing occurring.

Dr. B. A. Thomas, Philadelphia: It has been my experience that the injection of phenol is a useful procedure, in a large number of cases. I have noticed, however, that in not a few there has been a good deal of effusion as a result of the chemical reaction provoked in the tunica vaginalis, and in order to hasten convalescence I have resorted to secondary paracentesis. Has Dr. Herbst found it necessary to practice that supplementary procedure in the postoperative treatment of his cases?

Dr. Frank Hinman, Baltimore: Has Dr. Herbst made any comparative studies with the use of phenol and the

formaldehyd solution or catgut methods? A number who have used equal parts of formaldehyd, glycerin and alcohol report better results than with phenol. We have treated a few patients at Johns Hopkins with formaldehyd and with the pushing in of catgut, and there has been, in all cases, a marked inflammatory reaction afterward. We have not used phenol.

Dr. Robert H. Herbst, Chicago: Practically no pain follows the injection of phenol.

Concerning Dr. Lespinasse's trouble, I do not want to criticize his technic, but I imagine that he must have injected the acid into the dartos and not into the tunica vaginalis. I do not believe that sloughing could occur if the acid were injected into the tunica vaginalis.

Dr. Lespinasse: It was not my technic. The case was in the hospital when I went on duty.

Dr. Herbst: I happened to have had this accident occur in my own work due to the slipping of the sac from the end of the cannula. If one injects the acid into the tissues outside of the tunica vaginalis one is likely to cause a sloughing of the scrotum. Answering Dr. Thomas, a short extract from my paper reads: "These few were in most instances due to a slight reaccumulation of serum during the first week or two after injection, and after a simple evacuation the cure was permanent." I have not had any experience with the injection of formaldehyd solution.

SONOROUS VIBRATIONS IN THE TREATMENT OF EAR-DISEASES*

LESTER MEAD HUBBY, M.D.
NEW YORK

The treatment of ear-diseases with sonorous vibrations rests on the following principles:

The application of sonorous vibrations not too long continued and not too intense has a stimulating effect on the metabolism of all living cells. This action is a pneumovibratory massage. Applied to the ear it affects the external auditory canal directly, the tympanum through the membrana tympani, and the internal ear and cochlear nerve-system through the ossicles, oval window and, to a much less degree, through the tympanum and the round window.

All the structures of the auditory apparatus degenerate when insufficiently exercised; hence the necessity of intensive exercises when any of them are crippled.

Sonorous vibrations exercise the membrana tympani, the tympanic ossicles and muscles, the hair-cells of Corti's organ and membrana tectoria, and the entire cochlear nerve-system. Such exercise not carried to the point of fatigue increases the nutrition and efficiency of these structures.

The parts of the auditory apparatus or system, like those of other systems or organs of the body, are closely connected by the sympathetic. Metabolic changes in one part produce similar changes in allied parts. Thus, acute circulatory changes in the tympanic mucosa produce similar changes in that of the eustachian tube, and vice versa. This probably explains the improvement in the eustachian tube after treatment directed at the tympanum.

The Zünd-Burguet electrophone, which has been described in a previous paper,[1] was used in all the treatments and experiments enumerated herein. With this instrument siren-like scales may be produced in three timbers, corresponding to three registers of the human voice, low, medium and high. These registers may be lowered or raised, but they should be adjusted so that the scale of each overlaps that of the adjacent register. Each register has a scale of over an octave, and the sum of all the registers is a little less than five octaves, which is about the conversational range. If the harmonics and overtones produced are also considered, possibly the eleven octaves of human auditory perception are reached in the exercises. The latter consist in the production of scales in each of the registers, either applied to one ear at a time, or first to one ear and then to the other in each register, or as is usually done, alternately, first to one and then to the other ear while playing each scale in each register. Zünd-Burguet produces two scales, once in the low and once in the high register, and three times in the middle register at each treatment. Thus he starts in the middle register, proceeds to the low, then back to the middle, then up to the high and finally back to the middle register.

I complete the treatment by a short mechanical massage near and over the ear to overcome any slight numbness induced by the sonorous vibrations.

The intensity of the vibrations to each ear can be regulated, and also changed gradually or suddenly during the scales on each ear seriatim.

By this method, each note is produced for only a small fraction of a second (less than one-eighth of a second in the usual three-minute treatment), and each note is sounded at least twice for each ear.

The regulation of the intensities of the sounds used is exceedingly important. Zünd-Burguet as a general rule uses waves of not quite sufficient amplitude to cause a prickling sensation in the ear. There are many cases, however, in which no prickling sensation can be produced by the instrument used and yet the intensities of the sounds are sufficient to cause tinnitus and decreased audition. Therefore each case must be carefully studied and the intensities of the sounds graded to bring about the maximum improvement. To accomplish this in these cases, it is necessary to make tests before and after treatment for several days until the correct dosage is determined.

This brings up the subject of examinations.

The method pursued in chronic cases is to examine the ears at the start, and after fifteen, thirty, and fifty treatments.

In acute and subacute conditions, single tests may be necessary before and after treatment each time.

Thus the course and the frequency of treatments must be determined for each case, not always in advance.

Acute and subacute conditions require treatments once a day, while the chronic usually need two a day.

Good physical condition seems necessary for the most rapid improvement, especially when two treatments a day are given.

Negative results are liable to follow when the patient is in a continual state of exhaustion. This is one of the difficulties of the two treatments a day course. The pursuit of a vocation and the expenditure of the necessary energy for visits to the office twice a day sometimes prevent a successful outcome.

The usual course of treatment comprises fifty seances, two treatments a day. A second course of from twenty to thirty treatments is necessary in from six months to a year in the majority of cases of chronic deafness.

---

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[1] Hubby, L. M.: Treatment of Deafness with Sonorous Vibrations by the Zünd-Burguet Method, New York Med. Rec., Jan. 31, 1914.

Some experiments were tried on the fairly normal ear to show the immediate effects of the treatment on audition.

A single distance test with a watch, an acoumeter, or similar instrument was made just before and immediately after a treatment on six individuals with the following results:

Case 12.—Three cork acoumeter tests for each ear. The percentage of increase of audition distance varied from 1 to 45 per cent. The average was 21⅓ per cent.

Case 43.—Three cork acoumeter tests for each ear. Increase of audition distance 3 to 49 per cent. Average increase 20.5 per cent.

Case 28.—One watch experiment with one ear. Increase of audition distance 18 per cent.

Case 39.—Six cord acoumeter experiments with one ear. Increase of audition distance from 3 to 43 per cent. Average increase 13⅓ per cent.

Case 11.—Two acoumeter experiments for each ear. Increase of audition distance from 9 to 17 per cent. Average increase 14 per cent.

Case 13.—One cork acoumeter experiment with each ear. Increase of audition distance 13 and 9 per cent. Average increase 11 per cent.

The average increase for the twenty-six experiments was 16.33 per cent.

A few observations were made to determine the length of time that a normal ear retained its improved audition after one treatment and it was found to be a little over a day.

Some tests were made on abnormal ears to find the immediate effects on hearing distance.

Case 25.—A patient aged 60, suffering from otosclerosis with nerve atrophy. Right ear was tested three days with acoumeter, the left with cricket. Increase of audition distance from 4 to 47 per cent. Average increase 18⅓ per cent.

Case 4.—Patient aged 33, with otosclerosis, OMCC residual, nerve atrophy. One experiment with cricket with each ear. Increase of audition distance, right ear 61 per cent., left ear 46 per cent. Average 53.5 per cent.

Case 7.—Patient, aged 47, with otosclerosis and nerve atrophy. Cricket experiments on two days with both ears. Increase of audition distance from 3 to 22 per cent. Average 14.75 per cent.

The average increase for these three chronic cases was 28.9 per cent.

Case 39.—OMCA in boy aged 16. Tests made on seven days. On the first day a watch was used, on the other days a cork acoumeter. Increase of audition distance from —3 to 59 per cent. Average 14 per cent.

Case 28.—A man, aged 35, OMCA. Tests made on three days with watch showed increase of audition distance of 62, 60 and 13 per cent., or an average of 45 per cent.

SOME RESULTS IN CHRONIC PURULENT OTITIS

Case 17.—Man, aged 27, OMPC left ear with small perforation in Shrapnell's membrane. Usual antiseptic cleansing methods of no avail after several months' trial. Perforation healed in two days after four treatments.

Case 6.—Woman, aged 25, OMPC of both ears failed to dry after long course of treatment. Both ears dry after four days, eight treatments. She also had severe eczema of both canals which practically cleared up in two days.

Case 24.—Man, aged 22, OMPC (R). Ear dry after three days.

Case 8.—Boy, aged 5, OMPC (B), treated for over a year without success; both ears dry in five days' treatment, but the discharge returned with the next cold.

Case 15.—Woman, aged 30, OMPC (L), dry after three treatments.

Case 18.—Man, aged 22, OMPC and localized perilabyrinthitis in right ear. Dry after fifteen treatments.

Case 21.—Man, aged 54, OMPC (B) with almost entire destruction of the drum and ossicles, and exposure of the internal carotid on the left side. Discharge reduced to a few drops in a few treatments, but the ears did not become dry after forty-nine treatments.

Case 16.—Girl, aged 11, with radical mastoid wound following cholesteatoma, not healing in one spot after two months' treatment, became dry after fifty treatments.

Scanty dry ceruminous secretion causing itching of the external auditory canal was alleviated in at least one case of my series.

One bad case of eczema, associated with a moderate purulent discharge, was quickly relieved by the treatment.

Congestive, stenotic conditions of the eustachian tube were relieved in every instance in which the treatment was tried.

Case 1.—Woman, aged 66. Four pounds' pressure required to open right tube, and 14 pounds for left tube, before treatment. After fifteen treatments, less than 3 pounds' pressure required. (Three pounds pressure is the lowest pressure registered with my apparatus.)

Case 9.—Girl, aged 18. Left tube required 14 pounds' pressure to become patent, before treatment. After eighteen treatments the patency pressure needed was less than 3 pounds.

Case 19.—Man, aged 23. Left tube required 10 pounds' pressure to become patent, before treatment. After fourteen treatments the patency pressure needed was less than 3 pounds.

Case 33.—Woman, aged 25. Right tube required 15 pounds', left tube, 10 pounds' pressure to become patent, before treatment. After thirty treatments (no second test was made prior to this) the patency pressure needed was less than 3 pounds.

Case 37.—Girl, aged 19. Both tubes required more than 15 pounds' pressure to make them open, before treatment. After fifteen treatments the patency pressure required was less than 3 pounds.

Case 3.—Woman, aged 32. Right tube required 10 pounds' pressure to become patent before treatment. After fifteen treatments, less than 3 pounds was required.

Case 18.—Man, aged 22. Left tube required more than 15 pounds' pressure to make it patent before treatment. After thirty treatments 9 pounds' pressure was required, and after fifty treatments less than 3 pounds' pressure was required.

Case 17.—Man, aged 27. Left tube required more than 15 pounds to make it open before treatment; after fifteen treatments still not less than 15 pounds, but after thirty treatments less than 3 pounds were required.

Thus in the eight cases, four were relieved within fifteen treatments, one in eighteen, two in thirty, and one in fifty treatments.

TWO CASES OF ACUTE CATARRHAL OTITIS

Case 39.—Boy, aged 16. Severe OMCA (B). The first few days inflations were beneficial for the right ear, but there was decreased audition in the left. Sonorous vibrations improved the hearing rapidly. Hearing was normal in one week on both sides.

Case 28.—Man, aged 35. Severe OMCA (R). Audition was decreased by the mildest inflation, but attack was overcome by daily treatment with the sonorous vibrations for four days.

In the table are shown the audition tests at the first examination and the morning following the last treatment with sonorous vibrations in thirty-two consecutive cases of chronic deafness.

SUMMARY OF RESULTS

The results are thus roughly summarized:

Two cases of OMPC, audition distance tripled.

Two cases of OMPC with otosclerosis: Audition distance in one increased ten times; audition distance in the other increased 50 per cent.

One case of OMPC with nerve atrophy. Audition distance on one side increased over seven times and on the other side, four times.

One case of OMPC with localized perilabyrinthitis: Audition distance more than doubled.

Three cases of otosclerosis: Very slight improvement, less than 50 per cent.

Fifteen cases of otosclerosis with nerve atrophy: Five cases had audition distance more than doubled. Five had audition distance doubled or increased more than 50 per cent. Five cases had audition distance increased only slightly.

Eight cases of nerve atrophy: One had audition distance increased about ten times. Five had audition distance doubled. One had audition distance increased 50 per cent. One had audition distance increased only slightly.

High tone limit by air conduction was raised in twenty-five ears, remained stationary in five, and was lowered in four ears.

High tone limit by bone conduction was raised in eight ears, remained stationary in three and was lowered in three ears.

Lower tone limit by air conduction was lowered in twenty-seven ears and remained stationary in seven ears. Some of the latter might have been found lowered if they had been tested with a longer series of forks.

In only two cases of the series was any improvement indicated in ossicular rigidity by Gelle's test. One, Case 15, was an OMCC on one side and an OMPC on the other.

The other, Case 42, was a case of nerve atrophy.

These tests were made with a manometer, the amount of pressure necessary to affect the hearing for the C fork being noted.

Tinnitus was removed in nine cases, improved in twelve and in six there was no change.

Paresthesia, neuralgic otalgia, otitic cephalgia and sense of fulness in ears were removed in sixteen cases, improved in four and no change in one case.

The principal contra-indications for the treatment are acute purulent conditions of the tympanum, all acute conditions of the internal ear, great fatigue of the nervous system, and absolute nerve deafness.

The number of observations and tests enumerated in this paper are too small to permit the making of any sweeping generalizations, but are sufficient to show the usefulness of the treatment in many cases of acute and chronic conditions of the ears.

27 West Sixty-Eighth Street.

ABSTRACT OF DISCUSSION

Dr. Walter A. Wells, Washington, D. C.: In considering the effect of sonorous vibrations on the ear, some peculiarities of the ear as a sense-organ must be borne in mind. The auditory apparatus, which originated probably as a protective apparatus, is constantly on guard. The last of the sense-organs to go to sleep, it is the first to awake, and during waking hours, it has, apparently, no repose. Every one lives in a sonorous environment and must therefore have his auditory nerves constantly bombarded by vibrations of sound of every conceivable variety of pitch, quality and intensity. One may rest his eyes now and then by the simple, voluntary process of closing the lids. Hearing, however, is an involuntary function except so far as we may, by different degrees of attention, inhibit cortical perception. One inference from this is that an organ destined by nature to such increasing activities must suffer when it is deprived, as it is in deafness, of its accustomed stimuli of sonorous vibrations. It might also be inferred that an organ so constituted must be quite proof against fatigue and strain. The first inference I believe is a correct one, that a deaf ear suffers from a want of proper sound-stimuli, but, unfortunately, the second is not quite true, and therein comes the limitation of the therapeutic use of sound. I have not made use of acoustic exercises for the betterment of hearing, but I have endeavored to ascertain, in some measure, the behavior of the normal ear when exposed to sounds of different pitch, duration and intensity, hoping thereby to establish some of the laws of auditory fatigue, and I believe that a knowledge of the laws of auditory fatigue, as produced by sound, is an absolute preliminary requisite to the use of sound for therapeutic purposes. I first ascertained the exact electrical energy necessary to awaken a sensation of sound of a given pitch. This, which we call the threshold of excitation, is equivalent to the individual measurement of hearing for that sound. I then exposed this ear to electrically produced sounds of a selected pitch and a certain duration, and then, without loss of time, again tested the electrical energy necessary to awaken perception for the original note. Fatigue of hearing was clearly proved, though it was surprising how quickly it was recovered from. It was particularly marked for the higher notes of the scale. I employed only musical notes and continued them for comparatively short periods. Some who have experimented on animals, however, have proved that if we use very shrill disagreeable notes, for many hours continuously, we can actually produce degeneration in the nerve-cell, localized in the cochlea. In using acoustic exercises the greatest caution is necessary in order not to exceed the limit of auditory endurance as shown by the subjective sensation of the patient, and the evidences of fatigue as manifest by loss of function. The subjective sensation may be manifested by a generally disagreeable sense of irritability, a feeling of numbness and some form of tinnitus. The loss of function is ascertained by frequent, accurate functional tests.

The results reported by Dr. Hubby show that effects can be obtained, but I believe that he will agree that extreme caution must be observed in using sounds of the right quality, intensity and duration, and also discrimination in the choice of cases for this method of treatment.

Dr. L. M. Hubby, New York: It is, of course, very important to study each individual to see how he responds to the sonorous vibrations and then to give the proper length and strength of treatment. If Schambaugh's theory of auditory perception is correct, it would explain the good results obtained with this instrument rather than with those that have very few notes. The shortness of exposure to each note at a time and the covering of the entire scale within the limits of the instrument stimulate each corresponding part of the tectorial membrane with its adjacent hair cells without the production of fatigue.

Public Health and Good Roads.—In our largest cities to-day the economic health is directly dependent upon good transportation. More children die annually because of poor milk in the summer season than probably from any other cause. Fresh milk cannot be supplied to the children because of poor transportation facilities. It is true that a large part of this transportation is conducted by railroads; but a large part of this is also conducted by wagon roads. Transportation must be of the very best kind in order to bring fresh milk into our large cities. This in a measure also holds true for the smaller cities.—William De Kleine, *Public Health*, published by Michigan State Board of Health.

THE ETIOLOGY OF SPLENIC ANEMIA OR BANTI'S DISEASE

PRELIMINARY NOTE *

J. L. YATES, M.D.
MILWAUKEE

C. H. BUNTING, M.D.
MADISON, WIS.

AND

H. T. KRISTJANSON, M.D.
WAUWATOSA, WIS.

Pure cultures of diphtheroid organisms apparently identical with or closely related to the *Bacillus hodgkini* have recently been obtained by us from two spleens removed surgically in the treatment of splenic anemia.

Case 1 was under the care of Dr. J. J. Bellin of Green Bay, Wis., who kindly submitted blood-smears for examination before operation and sent the spleen immediately after its removal. The spleen was carefully sterilized externally by boiling before cultures were made from its interior.

Case 2 was a patient in the Milwaukee County Hospital, where the blood was studied before and after splenectomy and where part of the bacteriologic and experimental observations were made.

Histologic studies of the two spleens confirmed the clinical diagnosis of splenic anemia or the early stage of Banti's disease. Inoculation of dogs and rabbits was made with cultures of the organism obtained from Case 2 and with a culture obtained from a lymph-gland of a case of Hodgkin's disease, in which the diagnosis had been confirmed histologically and hematologically. In each case there were produced changes that were characteristic of the disease as described by Banti. These experiments were conducted independently at the pathologic laboratories of the University of Wisconsin and of the Milwaukee County Hospital and the results compared later.

These findings appear significant in view of the results of A. G. Gibbons,[1] who found in stained sections of six cases of splenomegaly Gram-staining streptotrichal organisms, at times segmented and at times appearing as bacillary forms.

The following clinical evidence seems confirmatory of the importance of the observations cited:

Atrophic cirrhosis of the liver, as a complication of the more usually accepted glandular variety of Hodgkin's disease, has been observed repeatedly, but is infrequent. Earlier stages of a periportal connective tissue overgrowth have, however, been noted comparatively often in the more chronic cases. This rarity of advanced cirrhosis in Hodgkin's disease is probably due, as Klein[2] has suggested, to the fact that life is, as a rule, insufficiently prolonged. In anemia splenica (Banti's disease) the first stage usually lasts from three to five years, a period quite in excess of the average duration of life in anemia lymphatica (Hodgkin's disease). This difference in duration, and in addition the relatively greater concentration of toxins in the portal circulation in Banti's disease, may explain why a Laënnec's cirrhosis is the constant terminal feature in the latter condition.

In the clinical course of splenic anemia as described by Banti[3] there is the characteristic alternation of periods of progression and remission which one of us[4] has described as so constantly present in Hodgkin's disease and has attributed to variations in the degrees of toxemia. There is the striking difference of greater chronicity in the former condition. Moreover, in splenic anemia recurrent fever has been noted which may correspond quite exactly with the febrile state first described by Murchison, but commonly designated as Pel-Ebstein.

Banti recognized that splenic anemia might be accompanied by lymph-gland enlargement in later stages and that the changes in the spleen in this affection and in pseudoleukemia-splenolymphatica were similar, wherefore he thought it possible to regard "anemia splenica as a pure form of pseudoleukemia splenica." In other words, Banti's disease might be Hodgkin's disease of the spleen.

The foregoing bacteriologic, histologic, hematologic and clinical evidence seems to warrant the conclusion that splenic anemia or Banti's disease and Hodgkin's disease are closely related, if not only variations in manifestation of a single type of infection.

THE USE OF ANTISTREPTOCOCCUS SERUM IN CHRONIC ARTHRITIS *

HOMER K. NICOLL, M.D.
CHICAGO

An extensive literature bears witness of the attempts which have been made in the past few years to make some use of passive immunization by means of antiserums against various forms of streptococcus infection. The serums prepared by Marmorek, Aronson, Moser and Menzer were perhaps given the most exhaustive trials. It appears that only a moderate and only a variable degree of success has been attained as compared with some of the effective immune serums, and it seems probable that some of the factors in the production or transfer of the immune bodies are at fault. The causes of this discrepancy have been sought in various parts of the immunizing process such as a lack of specificity in the organism used, the absence of polyvalence, insufficient dosage, and the apparently demonstrated fact that the streptococcus develops no true antitoxin, so that any immunity must be entirely phagocytic and would require frequent renewal of the specific *opsonins* in the immune serum to produce any permanent effect.

In view of the recent investigations which seemed to indicate that the streptococcus was a common agent in the production of the chronic as well as the acute forms of arthritis,[1] it was thought that possibly some of the defects of former serum treatment might be avoided and a serum produced which would be of benefit in some of the intractable cases of chronic joint disease. The serum used was a polyvalent horse serum prepared by Drs. Gatewood and Moore[2] working in the Otho S. A. Sprague Institute, the immunizing organisms consisting of from twenty-five to thirty strains of streptococci which had been isolated from the enucleated tonsils or the joint fluid of arthritis patients. The first portion of the serum used was not refined or heated. As toxic effects were observed following its use, an effort was made to lessen them by heating to 50 C. for ten hours and the serum was concentrated by a modified Banzhaf method[2] in order that the mass of each injection might be lessened. The original unheated serums were used in doses of from 20 to 30 c.c., and in a number of instances small preliminary injections of 1 or 2 c.c. were made from two to twenty-four hours before the large injection in the hope of avoiding allergic reactions by the production of a temporary refractory condition to anaphylaxis. This method did not appear to be successful in avoiding toxic symptoms; and, after several trials, a succession of gradually increasing frequent doses of 2, 6, 8, 10 and 12 c.c. was adopted as more likely to avoid dangerous sensitization. The maximum dose of the concentrated serum was not more than 12 c.c. since the viscosity of the serum prevented its rapid spread through the subcutaneous tissue and the use of larger amounts caused excessive pain.

[2] Heinemann and Gatewood: Jour. Infect. Dis., 1912, x, 416.

The serum was usually administered subcutaneously, in the interscapular region, a needle of rather large caliber being used. On three occasions the injection was made into the knee-joint after the withdrawal of fluid. In the subcutaneous injections every effort was made to avoid accidental intravenous injection. The needle was always withdrawn a short distance from its extreme insertion and suction made with the piston to determine if the point was in the lumen of a vein. The possibility, however, of tearing a vein with the broad point of the needle and of forcing in small amounts of the serum under the strong pressure necessary for the injection cannot be denied. The patients treated with the serum, twenty in number, were all in the Presbyterian Hospital on the service of Dr. Frank Billings and to a large extent in the beds maintained by the Sprague Memorial Institute. They received in conjunction with the serum the benefit of all possible measures for the relief of their symptoms, such as the removal of apparent foci of infection, complete rest in bed, a carefully regulated and nourishing diet, massage, streptococcic vaccines, the application of casts and braces, and an improvement of their mental attitude toward the disease. In all of the cases the disease was polyarticular, and all evidences seemed to indicate that the streptococcus was the infecting agent. The duration of the arthritis varied from one to fifteen years, the rage being about five years. The youngest patient 2 and oldest 56, seven of the twenty being under seven over 45. None gave a history of or hay fever and none had received any pre- jection of horse serum ry case, vaccines we used in conjunction serum, and whenever possible they were from organisms solated from foci of hich seemed probable sources of the sys- Most commonly they were from the infected sinuse of the head, or alve- pockets of peridental pus, and con- ococci in a mixture of the hemolytic varieties with small proportions of hylococci and Friedländer bacilli.

The vaccines were prepared in the usual manner and given in doses of from 50 to 200 millions at six or eight day intervals. They were usually given from twenty-four to thirty-six hours previous to the serum injections in the effort to have the serum present during the rising stage of the opsonins. In four of the cases extremely large doses, from 3 to 4 billions, were given for a short time, but no added beneficial result was observed.

The immediate results of the serum injections consisted of a sharp rise in the specific streptococcic opsonins and the clinical manifestations of serum sickness. At no time was there observed any especial relief from the pain and disability with which the patients suffered. The opsonins, especially with the first few large injections, rose rapidly to 1.5 to 2, and declined only after two or three days, usually never reaching the original level. After repeated injections, and especially with the smaller doses of serum, the rise was more gradual and steady. In every case the opsonins were maintained above the normal control by the combination of serum and vaccine. The phagocytic index was recorded and varied directly with the opsonins, although the variations were always less extensive. A slight rise in the number of leukocytes was observed in all cases in which the count was made following a serum injection, the highest number being 12,400.

Serum sickness, consisting of various degrees of headache, nausea, rise in temperature, aching of joints, and urticaria, was observed in eighteen of the twenty patients receiving the serum. The chief discomfort arose from the urticaria, which was very severe at times and recurred in some cases after each of the first three or four injections. Five of the patients developed rather marked symptoms of anaphylactic shock and in four cases it was so severe as to appear dangerous to life. The symptoms appeared in all cases within from one-half to three minutes after the subcutaneous injection, varying greatly in degree, the most constant ones being tingling and burning sensations in the face and hands, dyspnea with cyanosis, nausea and extreme weakness. In the more severe attacks, dyspnea and dysphagia were very marked and the pulse very weak and irregular. The duration of the acute attack was usually not more than three or four minutes, but in one instance the symptoms recurred in three lessening waves during a period of thirty minutes. This patient suffered the most severe shock, and during the first attack the respirations and pulse were entirely absent for a short period.

The hypodermic administration of epinephrin and the use of ammonia or some other stimulant was followed in the other cases by a speedy recovery. Morphin and atropin were also used with an apparently favorable action. Following the attacks, the patients complained chiefly of general malaise, and weakness, often with a severe headache. In one case an estimation of the opsonins was made with serum taken immediately after the shock, and a very low stage recorded. Reasoning from this observation, Dr. J. H. McClellan, who was assisting in the work, attempted to discover some constant relationship between a declining stage of opsonin and the occurrence of anaphylactic symptoms. It appeared after some observation that the injections given during a prolonged negative phase were more frequently followed by shock, and an effort was made in the later work to avoid this coincidence.

The anaphylactic symptoms occurred in four of these five cases and appeared to increase in violence. They did not appear with each injection but at intervals and never with the first injection. Among the five cases, it appeared first after the seventh, third, sixth, third, and seventh injections, the time which had elapsed since the last preceding dose varying from two to twenty-six days. In all, eight severe shocks were observed. The opsonic curve in these patients did not vary markedly from the average of the other fifteen cases.

The later or final results of the use of the serum are difficult to estimate because of the simultaneous use of so many other remedial agents. In the majority, especially when the process was not of too long duration, there has been a definite improvement, and in some the change has been remarkable.

In comparison with an equal number of patients at approximately similar stages of the disease who were in the hospital at the same time and who received identical treatment with the exception of the serum, no very definite advantage could be observed. The opsonic indexes of those who did not receive serum did not rise, as a rule, so rapidly, and it appeared that the serum and vaccine had some complementary action when given together. When considered over a long period of time, however, their opsonins remained as consistently high, and the clinical improvement was apparently as pronounced as in the serum patients. It appeared at least that any added gain from the use of the serum was not sufficient to compensate for the severe pain and discomfort attending its administration and the dangers of the anaphylactic shock.

In addition to our cases, Dr. J. J. Moore of St. Luke's Hospital administered the serum to four patients suffering with chronic arthritis probably of streptococcal origin. The treatment differed from ours in that the serum was the only therapeutic agent employed over periods ranging from two to eight weeks. In no instance was there any improvement which could be accredited to the serum. One patient had an acute inflammatory arthritis involving the ankle, toe, and finger joints during the course of serum treatment. Although this patient received from 10 to 15 c.c. of serum daily, the joint inflammation persisted. In a second case in which the tonsils had been removed before serum therapy was commenced, the throat became acutely inflamed and persisted for some time in spite of the administration of serum. In this case a virulent hemolytic streptococcus was isolated from the throat.

The reactions following the serum injections were usually mild, local in character, often nothing more than an erythema, or pruritis around the site of injection. An edema of the lower limbs was observed in one patient following daily doses of 10 to 15 c.c. of the serum. This was thought to be a peculiar allergic reaction since the heart and urine were normal. There was no definite rise in the opsonic index in any of these patients during the serum treatment.

CONCLUSIONS

1. The administration of horse serum in repeated doses may be followed in 25 per cent. of the cases by dangerous degrees of anaphylaxis, even in patients who give no history of previous use of horse serum or of asthmatic symptoms.

2. Heating and aging the serum does not completely remove its toxicity.

3. Clinical observation and the estimation of immune bodies do not show any added advantage from the use of an antiserum in chronic arthritis even when a concentrated serum with much greater potency than the usual commercial serums was employed. In two cases, acute streptococcus infections arose during and in spite of its administration.

4. Attempts to increase the value of such a serum by concentration have not been successful, so far as its employment in chronic arthritis cases is concerned. Whether or not such concentrated serum might have advantages in acute streptococcus infection has not been determined.

5. In view of these facts, the use of antistreptococcus serum in the treatment of chronic arthritis is, under present conditions, neither advisable nor justifiable.

XII

DISINFECTION OF SCHOOLS

In view of the fact that contact is apparently a necessity for the spread of almost all, if not all, of the contagions that visit schoolchildren, disinfection, as so long practiced, is unnecessary and a delusion. Also the closing of schools is unnecessary. Fumigation of schoolrooms and schoolbuildings has been abolished in many large cities. The ordinary care of the schoolroom involves the free admission of sunlight and pure air and the removal of dust by a vacuum cleaner or by moist sweeping or mopping.

If a contagious disease occurs, (*a*) the child's desk, chair, and the immediately surrounding desks and chairs, as well as the floor, should be sprayed and washed with a strong solution of a germicide or disinfectant. (*b*) The child's books, pencils, etc., should be destroyed, unless the books are valuable, in which case they should be subjected to dry heat or to formaldehyd cabinet fumigation. (*c*) The pupil's clothing should be boiled or efficiently fumigated before he returns to school.

There is no question that most all so-called children's contagious diseases are more prevalent during the months that schools are in session than during vacation times. Hence schools do distribute infection by allowing crowding and close association with infected persons; also because the confinement diminishes the resisting power of the well. Therefore, the necessity for cleanliness, freedom from dust and for fresh air and sunlight is readily recognized.

DISINFECTION

Fresh air and sunlight let freely into infected rooms and into the sickrooms aid in killing germs and curing the patients. Schoolrooms with open windows and open-air schools have less contagion than ordinary schoolrooms.

Oxygen is not a very active bactericidal agent. Ozone if brought to the germ is effective, but pure ozone is difficult to furnish to infected rooms or to introduce into infected parts of the body, and ozone treatments of infection are generally fallacious and fraudulent. Hydrogen peroxid solutions, if fresh and uncontaminated, are efficient in killing germs, when brought into contact with them. To be efficient the strength should be 50 per cent. of aqua hydrogenii dioxidi.

Fumigation after scarlet fever, diphtheria and measles does not seem to pay for the cost and trouble it causes, and should be abolished. Proper fumigation with strong formaldehyd, carried out by boards of health, should still be done for small-pox and tuberculosis, and perhaps for erysipelas, childbed fever and tetanus, especially in hospitals. Spraying with germicides of all the immediate surroundings of an infected patient is the method of disinfection now most satisfactory. All washable clothing and bedclothing should be boiled: all other clothing should be baked and put into the sunlight. Carpets and rugs should be washed with antiseptics. Various washing solutions may be used, such as chlorinated lime solutions, 5 per cent., formaldehyd solutions, corrosive sublimate solutions 1 : 500, 5 per cent. phenol (carbolic acid) solutions, or better, the higher coal-tar disinfectants, as liquor cresolis compositus. The New York Board of Health orders the woodwork and floors scrubbed with hot solution of 1 pound of washing soda to 3 gallons of hot water. Bedding and night clothing are ordered soaked in phenol solutions and then boiled in soapsuds for half an hour. Books and toys should be burned.

Dr. Dixon,[1] Commissioner of Health of Pennsylvania, suggests as a substitute for the combination of potassium permanganate and formaldehyd, the following: "sodium dichromate, 10 ounces avoirdupois; saturated solution of formaldehyd gas, 1 pint; sulphuric acid, commercial, 1½ fluidounces." He states that the sulphuric acid and formaldehyd gas form a stable solution. "This, after it cools, should be poured over the crystals of sodium dichromate spread out in a thin layer over the bottom of an earthenware vessel having ten times the capacity of the volume of the ingredients used." He finds this process more rapid than the combination with potassium permanganate.

The danger to others lies in carriers and missed cases, those who are so mildly sick as to escape medical care.

The contagious disease hospital is the only safe place for tenement cases; this prevents the infection of others, as families in tenements have no isolation rooms and no trained nurses to carry out disinfection.

PERSONAL HYGIENE OF SCHOOLCHILDREN

The schoolteacher and the trained nurse should note and correct many things found wrong in a child. They should also teach many simple truths as to hygiene. Only a few obvious hygienic mistakes will be touched on before conditions that may cause infection of others are discussed.

Feet.—A good working rule is for broad-toed shoes always; no heels for the earlier years of the child; low heels later; and if must be, still later, heels a little higher. Rubber heels are all right if desired, but not rubber soles, unless perhaps for playing tennis. The weight of a rubber-soled and heeled shoe is too great for constant, or even for a few hours' continuous use. Also, completely rubber-soled and heeled shoes cause the feet to perspire, to say nothing of the undesired insulation of the person. Low shoes for summer, high shoes for winter and rainy weather, and storm shoes or rubber overshoes for rain and snow are necessities for health. If a child wears rubber boots in stormy weather, they should be removed while in school. Occasional observations of a child's feet and insistence that proper shoes be worn will prevent future corns, bunions and weakened arches. Too short and too narrow-toed shoes ruin the feet of young men and young women. Also, this continuous dancing fad causes corns and callouses to occur on different parts of the toes, which means future trouble, if not properly cared for or prevented.

Hygiene of the Skin.—Briefly to refresh our memory as to the anatomy and physiology of the skin, it may be noted that the different layers of the cells of the epidermis, or horny layer of the skin, change their chemical structure as they advance to the outer layer. They gradually die, so to speak, and then are cast off. This layer contains no blood-vessels and no lymph-channels, and is a distinct protection to the body against the absorption of toxins and germs. If this layer is broken by injury, an absorptive area is immediately presented, and infection may readily occur. Nature makes this protective layer thickest where injury is likely to be the greatest, such as the palms of the hands and the soles of the feet. The hair and nails are really projections of this layer of horny cells.

Some drugs in solution or ointment may be rubbed or massaged through the horny layer into the layers of absorption, that is, the rete layer. Irritants may also reach this layer after more or less corrosion or removal of the epidermal layer, and local inflammation may be caused. It is the rete layer that is especially inflamed in many conditions of eczema.

The sebaceous glands of the skin may be overactive or underactive. If they are overactive, too much oily substance reaches the skin and hair and the parts become greasy. If the opening of a gland becomes clogged with dust or other particles, the canal and gland become more or less congested and the result is a so-called comedo or blackhead, and pathogenic germs may grow, especially the pus-forming germs, and a condition of acne or infection occur. If these sebaceous glands secrete insufficiently, the skin becomes dry and scaly, perhaps brittle, cracks readily, insensible perspiration is interfered with, and the whole system may be more or less affected, depending on the seriousness of this condition.

The sweat-glands must be sufficiently active for the body to be in perfect health; they largely eliminate water, reduce the temperature of the body and keep the internal temperature normal. The few salts and the small traces of nitrogen that are eliminated by the sweat-glands may be disregarded; suffice it to say that the excretion of poisonous nitrogen compounds by the sweat-glands is very small. The odor of the perspiration varies with different individuals and with different races. Not infrequently it is intensely disagreeable, and the secretion, both as to odor and character and the amount of decomposition of fatty acids, varies with the part of the body from which the perspiration comes. When the sweat from an individual gives off a very disagreeable odor, the condition is termed bromidrosis, and requires treatment by a physician. The condition should be noted in children, and prevented if possible.

Dandruff and dirty, greasy scalps and insufficient cleanliness of the hair should be noted, and instructions given as to the proper care of the child's head. A good daily brushing, and a simple castile soap shampoo weekly (or at least once in two weeks), with proper drying of the scalp, should be given by the mother.

---

[1] Dixon, S. G.: A Substitute for Potassium Permanganate to Liberate Formaldehyd Gas from a Water Solution, The Journal A. M. A., Sept. 19, 1914, p. 1025.

Besides the advice given the parents as to the care of the child's scalp, the teacher or nurse should note the condition of the child's skin as to cleanliness, greasiness, dryness or eruptions, and proper advice should be transmitted to the parents. Also, the condition of the clothing and the kind of underclothing should be noted, especially in young children, and if considered improper, similar advice should be given the parents on the subject of underclothing.

Children and parents should be instructed not to use strong, irritant soaps, and parents should be urged to seek medical advice when a child's skin is too greasy and acne of the face is beginning to develop, when the child's skin is too dry for health, and when there is any eruption. They should be warned against the use of all nostrums, whether ointments or liquids, as liable to cause more harm than good. Parents should be advised to give their children only the simplest kind of food, to give them no tea and coffee, and to forbid their eating large amounts of sweets; especially is such advice necessary when there are eruptions on the skin.

Contagious Skin Diseases—The principal contagiums that occur on the skin of schoolchildren are ringworm, body- and head-lice and scabies. None of these conditions can be well treated at the school or in dispensaries, but the treatment must be carried out at the home of the infected child. No verbal or written instructions will accomplish half so much as a visit from the trained nurse and her personal instruction of the parents. Also she can take a general survey of the other children of the family and of the household.

It is not necessary to describe the treatment for these several troublesome but simple conditions. The various parasiticides are well understood, but the whole success of treatment lies in the care exercised and the curative measures taken in the child's home. When the patient's family can afford it, the Roentgen-ray treatment of ringworm is perhaps the ideal treatment.

Body-lice rarely occur in children and demand a cleansing bath and the baking of the underclothing in an oven at a temperature above the boiling point, but not high enough to burn the clothing.

Pediculosis Capitis.—Aside from being an evidence of neglect, the head-louse may be the means of conveying infection, for example, of typhus fever.

Dr. Jacob Sobel[2] of the Department of Health of New York City describes the method of handling this infection in New York, and also shows how greatly the disease has been reduced by the home instructions that the board of health has inaugurated. Following are the instructions issued by the New York board of health to the parents of children who are found to be infected with pediculi:

> Children affected with vermin of the head are excluded from school. The following directions will cure the condition:
>
> Mix ½ pint of sweet oil and ½ pint of kerosene oil. Shake the mixture well and saturate the hair with the mixture. Then wrap the head in a large bath-towel or rubber cap so that the head is entirely covered; the head must remain covered from six to eight hours.
>
> (Tincture of larkspur may be used instead of oil mixture. The directions for use are the same.)
>
> After removing the towel, the head should be shampooed as follows:
>
> To 2 quarts of warm water add 1 teaspoonful of sodium carbonate. Wet the hair with this solution and then apply castile soap and rub the head thoroughly about ten minutes. Wash the soap out of the hair with repeated washing of clear warm water. Dry the hair thoroughly.
>
> Nits: If the head is shampooed regularly each week as above described, it will cure and prevent the condition of "nits."

Vulvovaginitis.—Just what methods are advisable to determine that a female child has vulvovaginitis, which may be transmitted to others by the school water-closets and by other means of transmission, is difficult to outline. It must be recognized, however, that a great deal of this condition occurs in young girls. The discharge may be non-specific, or may be associated with some eruption or irritation of the genital region, or it may be actually due to an infection from gonococci. Microscopic examination and bacteriologic cultures are the only means of determining the character of the discharge.

It being ascertained that a girl has a discharge, it is the duty of the medical inspector or trained nurse to insist that the family have their physician properly treat the patient. The necessity of bacteriologic examination must be emphasized, the danger of contagion urged, and the necessity for ascertaining the source of the child's infection discovered, if possible.

It is certain that these little patients frequently masturbate; whether this is a cause of the inflammation, or whether the irritation causes the bad habit, is a matter of unimportance. Feeble-minded girls are likely to have a vaginal discharge, and have been found to be often infected with gonorrhea.

Dr. F. G. Taussig[3] urges the following measures to prevent the vaginal infection from entering institutions such as orphan asylums and children's homes:

First, he would examine a vaginal smear from all girls applying for admission, and if gonorrheal infection is discovered, the child should be excluded until cured. If the disease is discovered in an institution, the patient should be isolated and the nurse in attendance should take measures to prevent the infection of others.

As further preventive measures of gonorrheal infection of female children, Taussig advises that 1 drop of a 2 per cent. silver nitrate solution be instilled into the vestibule of the vagina at the birth of every female child whose mother shows evidence of gonorrhea. He would advise this even if only about 5 per cent. of gonorrheal vaginitis in young children occurs directly after birth. He also believes that "the adoption of the U-shaped seat with low bowl and other precautionary measures to prevent the spread of the infection in the lavatories in schools, playgrounds, comfort stations and tenements" would prevent a great many cases of innocent infection.

The curative treatment is the gentle, frequent cleansing douche, as warm boric acid or borax solutions, and the more or less frequent applications of silver salt solutions. The little patient should not be considered cured until several examinations of the smear have shown gonococci to be absent.

(*To be continued*)

GASKELL AND THE PHYSIOLOGY OF THE HEART

The stirring events of recent weeks, when men's minds have been turned from the paths of intellectual life into other fields of human activity, should not make us oblivious of the names which deserve honor because of what they represent in science. For this reason we shall not forego the opportunity to refer to the death of Dr. Walter Holbrook Gaskell at his home in England, Sept. 4, 1914, at the age of 67 years. To this talented physiologist, stimulated by the environment of the Cambridge school under the influence of Michael Foster and trained in Ludwig's laboratory at Leipsic, we owe some of the fundamental observations regarding the mechanism of the phenomenon known as heart-block — a condition to-day recognized clinically and studied experimentally wherever the medical sciences flourish. It was Gaskell who invented the term "heart-block" and produced it experimentally by clamping the auriculoventricular and sino-auricular grooves, which he calls "the two natural blocking points" of the muscular contraction wave. One of his biographers, Dr. Fielding H. Garrison of the Army Medical Museum in Washington, has summarized the importance of Gaskell's endeavors in this field as follows: In his view, the original Stannius experiments become simple cases of temporary block. This view has been brilliantly confirmed by the discovery of the vestigial muscular structures known as the auriculoventricular bundle of His and the sino-auricular node of Keith and Flack; also by the clinical and pathologic findings in the disease described by Morgagni in 1761 and now known as heart-block or the Stokes-Adams syndrome. Gaskell even produced the two-, three- and four-time gallops of modern clinicians, in which the ventricle drops one or more of its beats. Schiff's observation that the ventricle of a dying heart beats slower than the auricle is interpreted as the effect of a gradually increasing block. Gaskell also produced the clinical condition known as "fibrillation of the heart" in an isolated strip of cardiac muscle, interpreting the phenomenon as due to blocking of the connections between individual muscle cells. In recent medicine, the various rhythmic disorders of the heart are regarded, not as cases of nervous unbalance, but as the effects of blocking of the peristaltic wave which passes from sinus venosus to bulbus arteriosus, and from muscle fiber to muscle fiber.[1]

In these days, when the relative merits of the neurogenic and myogenic hypotheses of the causation of the heart-beat are still being debated vigorously, we may recall that it was the early work of Gaskell and of Engelmann in particular that furnished serious objections to the neurogenic thesis earlier supported. These physiologists came to the conclusion that the source of the cardiac rhythm was to be found, not in the ganglia scattered about its cavities, but in the muscular cells themselves. It was their contributions which inaugurated the revival of the myogenic theory.

Aside from these classic researches on the motor mechanism of the heart, science owes to Gaskell numerous important contributions to other chapters of biology, notably on the sympathetic system and on organic evolution. To those who appreciate the confusing detail in the factors concerned in the latter field, the trend of Gaskell's mind may be described by his ability "to state the problems in terms of biologic phenomena rather than in metaphysical terms."[2]

THE PITUITARY BODY

The discovery by Marie[3] that an intimate relationship exists between the pituitary body and acromegaly created a new interest in a body which previously had been of interest purely on account of its anatomic relations and its histologic structure. About a decade later Oliver and Schäfer[4] found that extracts made from the entire pituitary body produced a rise in blood-pressure when given intravenously. By working with extracts made from its various parts, Howell[5] concluded that the pressor effect was produced only by posterior lobe extracts. Later it was found by others that posterior lobe extracts caused diuresis, dilatation of the pupil, an increase in the secretion of milk and the contraction of unstriped muscle, especially that of the arteries, uterus, intestines and bladder.

The evidence that the pituitary body is essential to life is now convincing. Paulesco[6] and Cushing,[7] using an improved technic, showed that fatal results are to be expected from removal of the anterior lobe. Partial removal of the anterior lobe led to striking changes in metabolism.

7. Cushing, Harvey: The Hypophysis Cerebri, The Journal A. M. A., July 24, 1909, p. 249.

The knowledge that extracts of the anterior lobe, which is glandular in structure, are without marked immediate effects when injected intravenously, whereas extracts of the posterior lobe, which is a nervous structure, produce striking immediate results is very interesting when one considers that removal of the posterior lobe is compatible with life, while removal of the anterior lobe terminates fatally.

Feeding experiments have not been wholly satisfactory. Wulzen[8] has recently found that when young fowls were fed with anterior lobe substance a retardation of growth resulted. This effect was especially marked in males.

From a therapeutic point of view the most striking results have come from the administration of posterior lobe extracts. Favorable results have been reported by many from the use of posterior lobe extracts in the treatment of post-partum hemorrhage, uterine inertia and postoperative shock: on the other hand, its use in labor is in certain cases followed by grave results, rupture of the uterus being reported after the repeated administration of some commercial preparations.[9]

The recent work from the Hygienic Laboratory by Roth[10] of the Public Health Service on the standardization of pituitary extracts may throw some light on some of the results obtained in therapeutics. Roth examined preparations obtained from six different manufacturers and found that the activity of commercial posterior lobe extracts varied widely when tested by three different methods, their relative activity on the isolated uterus of the guinea-pig being as 7.5 to 1. The commercial preparations which have been responsible for untoward results have therefore been shown to be exceedingly active ones. Roth could assign no positive reason for such great variability. He concludes that there is need for uniformity in the strength of commercial pituitary preparations, and to bring this about advocates their standardization on the isolated uterus of the virgin guinea-pig, suggesting an arbitrary standard. He further suggests that clinical studies should then be made to determine the therapeutic dosage.

AN INTERRELATION BETWEEN OXYGEN AND CARBON DIOXID IN THE BLOOD

Among the numerous illustrations of physiologic regulation in the functions of the body none exhibits a greater degree of exactness than those furnished by the absorption and dissociation of the gases of the blood. With respect to the relation of oxygen to the circulating medium this has been demonstrated more strikingly perhaps than is true in the case of the carbon dioxid which ordinarily accompanies it. With the demonstration of the unique rôle of the latter gas in regulating respiration, and presumably other activities of the organism, has come an increasing knowledge of its exchange between tissues, blood and external atmosphere, respectively. The average arterial blood, in which the hemoglobin is 96 per cent. saturated, contains 17.76 c.c. of oxygen in combination per hundred c.c. of blood, or a total of 18.1 c.c. if to this is added the small amount of the gas which is in simple solution at the oxygen pressure of arterial blood. Under normal conditions the same individual shows a definite and constant relation between the pressure of carbon dioxid and the amount of this gas taken up by fresh defibrinated human blood. It does not differ much for different individuals. According to Christiansen, Douglas and Haldane,[1] at 40 mm. pressure of carbon dioxid, 100 volumes of oxygenated human blood take up about 50 volumes of carbon dioxid; and at about 80 mm. pressure 15 additional volumes are taken up.

These investigators, working in the Physiological Laboratory at Oxford and the Institute of General Pathology at Copenhagen, have demonstrated that at a given pressure of carbon dioxid, blood which has been deprived of oxygen takes up considerably more carbon dioxid than oxygenated blood. The oxygen—and the same is true for carbon monoxid—thus tends to drive out carbon dioxid, and this action depends on the saturation of the hemoglobin. For the metabolic performances of the organism it is interesting to learn that the oxygenation of the blood in the lungs helps to drive out carbon dioxid, and increases by one-half or more the amount of carbon dioxid given off at each round of the circulation. The deoxygenation of the blood in the tissues in turn helps the absorption of carbon dioxid and diminishes by about 40 per cent. the rise of carbon dioxid pressure in the venous blood.

If these facts are correct it follows that the giving off of carbon dioxid by the lungs is to a large extent consequent on the taking up of oxygen. Haldane and his colleagues have insisted for some time that under a variety of conditions the uptake of oxygen may be supported by physiologic activity of the lung epithelium. Under such conditions, therefore, the giving off of carbon dioxid would also be dependent on this activity. In any event these interrelations between the movements of the two gases, long ago suspected and now more definitely demonstrated, give an added illustration of the interdependence of many physiologic functions in the organism.

In connection with the investigation of the behavior of carbon dioxid in human blood,[1] it has been possible to calculate the rate of blood-flow through the lungs. Every one must realize, from general considerations, that this involves rapid change. The statement that the rate of this blood-flow may amount to 7.7 liters (8.1 quarts) per minute for a person with a total blood volume of 4.7 liters (4.9 quarts) offers a concrete instance of the marvelous performances of the human circulation.

SOURCES OF CEREBROSPINAL FLUID

It has been thought that the cerebrospinal fluid is derived from the choroid plexuses and possibly also from the nervous tissues by way of the perivascular spaces, but conclusive evidence as to its source has been lacking until recently. Thus Dandy and Blackfan,[1] and also Frazier and Peet,[2] have produced internal hydrocephalus in animals by blocking the aqueduct of Sylvius. Then Weed,[3] under the direction of Cushing, took a step nearer to the final solution of the problem by introducing a cannula directly into the third ventricle from the fourth. When the cannula is introduced there is at first a rapid flow of several drops, whereupon a gradual diminution ensues, and after three or four hours, all flow ceases. The fluid obtained in this way appears identical with that in the subarachnoid spaces. By Weed's method it will be possible to study the action of drugs and other factors on the production of fluid, that is, on the functions of the choroid plexuses.

Around the cerebral vessels are spaces which extend to the capillaries and communicate into the subarachnoid spaces. If the direction of the flow of the fluid in these perivascular spaces could be determined, light would be thrown on another possible source of the cerebrospinal fluid. By subarachnoid injection according to the method already discussed in these columns,[4] Weed found no granules of Prussian blue in the perivascular spaces after injection at low pressure. After injection under medium pressure granules were found in the perivascular and pericapillary spaces, not, however, in the vessels, but sometimes adhering to the periphery of the nerve cells and their prolongations. On injection under high pressure, granules sometimes were found in the lumen of capillaries. These results point unmistakably, it would seem, to a flow from the capillaries into perineuronal and perivascular spaces and thence into the subarachnoid spaces, where the fluid mixes with that from the ventricles.

These results point clearly to a dual source of the cerebrospinal fluid, namely, the choroid plexus and the cerebral capillaries. It will be recalled that by the same method of subarachnoid injection, Weed[4] could demonstrate that the cerebrospinal fluid escapes largely by way of the longitudinal sinuses, and also along the nerves. These results certainly go far to give us a clear idea of the circulation of the fluid.

THE CORPUS LUTEUM AND OVULATION

Aside from the immediate scientific value of the experiment, there is a peculiar sort of satisfaction in being able to duplicate new facts found in one species of animals by observations on another species. Whenever a process or a structure is seen to be common to many types, the frequency of its occurrence gives a justification for belief in its universality. It is often asked whether physiologic or pathologic phenomena noted in the dog, cat, rabbit or other laboratory animals are safely referable, under similar conditions, to man. The more wide-spread such phenomena are in the animal kingdom, the more justifiable is the reliance which we feel in upholding the belief in their broad applicability. Comparative physiology and pathology deserve the earnest consideration of the student of human biologic manifestations.

In view of what has just been said, there is a special satisfaction derived from the report that the desiccated fat-free substance of the corpus luteum of the cow, when injected in suspension, in proper dosage, into an actively laying fowl immediately inhibits ovulation. The duration of this effect varies with different birds from a few days up to two or three weeks. After the bird begins ovulating again the laying goes on unimpaired. The same effect is produced by the injection of extracts of the lutear substance, either intravenously or intra-abdominally. The active substance producing the inhibition is inactivated by boiling.[1] As Pearl and Surface,[1] who ascertained these facts, point out, the ovulation-inhibiting function of the corpus luteum is specific in a physiologic or chemical sense. The fact that the same chemical substance inhibits ovulation in mammals and birds, the latter of which do not possess any organ corresponding to the one which produces the substance in mammals (the corpus luteum), suggests that natural selection probably had nothing to do with the evolution of either the organ or the function in the mammals. If it had, one would expect that the function would have been perfected as a specifically and exclusively mammalian one.

The chief interest, to the student of medicine, in the effect of corpus luteum substance on ovulation in the fowl lies in its corroboration of the well-known work of Leo Loeb[2] on mammals. He has shown that one function of the well-developed corpus luteum in the mammalian reproductive cycle is to inhibit ovulation. To the confirmation which this finding has already received, these new studies in avian reproduction give added support. The corroboration of one more instance of an important physiologic function specifically controlled by a chemical regulation is in line with recent developments. It suggests, to quote Pearl and Surface, that since it is possible to obtain a chemical substance which inhibits ovulation, without in any way otherwise affecting the normal vital processes of the bird, it will also probably be possible to find a chemical substance which has the opposite action and will stimulate, or better activate, the ovulation mechanism.

"MOTHERHOOD WITHOUT FEAR"

A few months ago *McClure's* magazine announced to the prospective mothers of the country that a remarkable discovery had been made by which the pangs of childbirth were to be forever abolished. The announcement was made in the form of an article by two women, apparently of no medical training. The remarkable discovery was the long-discredited scopolamin-morphin analgesia, first suggested in 1902. This sensational article was taken advantage of by a pharmaceutic firm for free advertising of a nostrum, based on a similar formula; a number of physicians previously unknown brought themselves into newspaper prominence with naive statements regarding their ability in the use of the method and with reports of their success; a host of "sob-writers" and sisters of the pen, whose work is tested by their ability to wring anguish from sympathetic hearts, filled columns of the daily press and magazines with pseudoscientific rubbish.

And now, when this sensation has about died out, we are supplied with another. This one is furnished by Mr. Vance Thompson, playwright and novelist; the medium is the *Cosmopolitan* magazine. In an editor's note the article describing this new method of eliminating the pains of labor is introduced as follows:

> The all-absorbing events of the last days of July prevented the spread of the most joyful message ever sent from the scientist's laboratory to woman. It was that henceforth she will bear children not in pain and terror but in gladness. Paris knew of it; the French Academy of Medicine had accepted it, but it got no further. Mr. Thompson was then in the city and to him has fallen the wonderful opportunity of carrying the good news to the men and women of America. Here it is.
>
> Attention must be called to the fact that the practice here described has nothing to do with the morphin-scopolamin treatment originating some years ago in Freiburg and which recently has had some measure of exploitation under the popular name of "twilight sleep." This requires special and very expert care on the part of the physician, and has the further disadvantage of drugging the patient into a state of partial insensibility. It can be administered properly only in hospitals, and its use in general practice should, and probably will, be forbidden by law. But detoxicated morphin, without the slightest danger to the mother, causes neither check nor delay, does not interfere with the necessary rhythmic muscular contractions, and makes painless childbirth a scientific certainty.

As a composition, Mr. Thompson's article is fairly comparable with that of the two ladies who reintroduced "twilight sleep" to American women; but for sentimental rot, for pseudoscientific rubbish, and for downright "sob-writing" Mr. Vance Thompson must be given the palm.

As to the facts, in one place it is stated:

> I do not write of this discovery as being in an experimental stage. It has been accepted by the French Academy of Medicine — the date was the third week in July. Surgeons, gynecologists, chemists, doctors of all degrees have examined, tested, approved. For once scientific men have been unanimous.

There is no excuse for such false statements; even Mr. Thompson could easily have learned the truth.

What are the facts? What is this "detoxicated morphin" which, we are told, eliminates the pains of childbirth? Last July, Ribemont-Dessaignes reported to the Academy of Medicine of Paris a number of cases of childbirth in which he had used, for the relief of pain, a preparation "discovered" by a chemist named Paulin. The nature of the preparation was not disclosed to the academy. September 1, presumably as a result of the suggestion of Paulin, a request came to the academy from the Minister of War asking the opinion of the academy as to the advisability of using this remedy, presented under the name "Tocanalgine" and "Antalgine," in military hospitals as a substitute for morphin. By unanimous vote the academy declared that, the formula and composition of these medicines being unknown, it could give no opinion. Since it was stated, however, that the new drug was produced by the action of enzymes on morphin, the academy appointed a committee to investigate oxydimorphin, a chemical substance which it was known could be produced by the action of enzymes on morphin. Under the direction of the committee, two chemists examined samples of the new preparation obtained directly from the discoverer. The examination showed that these samples were variable, and that they did not contain any oxydimorphin. The only active ingredient found by these chemists was morphin hydrochlorid, and this in quantities varying from 0.05 to 4 per cent. The conclusions of these two chemists were later emphasized by Bertrand who, after careful chemical and biologic tests of samples submitted to him, found that the solid residue was exclusively formed of hydrochlorid of morphin, and that it was fully as toxic and dangerous as morphin, as might be expected; the symptoms of poisoning were exactly the same as those of morphin hydrochlorid, and death occurred after the same interval. A dose of the preparation would give about ½ grain of morphin. In other words, judging from the reports which appeared in the *Journal de pharmacie et de chimie* for November 16, and the

Bulletin de l'Académie de médecine from July 21 to November 17, this so-called "detoxicated morphin" is essentially a solution of morphin in ampules. It will kill just as quickly as morphin, it will relieve pain just as quickly as morphin — because it is morphin. Naturally, the Academy of Medicine of Paris has not accepted the preparation.

We presume it is useless to protest against this shameless exploitation of the fears of prospective mothers of the country. But if magazines must have articles on this subject, let them at least confine themselves to the facts. The article in the *Cosmopolitan* is cruel, sensational and a disgrace even to yellow journalism.

Current Comment

CONGRESS PASSES ANTINARCOTIC BILL

The Harrison bill (H. R. 6282) for the suppression of illicit trade in habit-forming drugs passed the House December 10, after having been before Congress for over two years. The passage of the first and second Harrison bills regulating the manufacture and importation of habit-forming drugs has already been mentioned in The Journal.[1] The third measure, to regulate the interstate sale of opium and cocain preparations, passed both houses last summer, but on account of conflicting amendments was referred to a conference committee. This committee agreed on a report which was adopted by the Senate. When the report came up in the House in the last hours of the recent session, the question of no quorum was unfortunately raised, and the House adjourned without action. The bill consequently went over until the present session. The object of the bill is to restrict the sale of habit-forming drugs to persons desiring them for legitimate purposes. The difficulty has been so to word the measure as to prevent illicit traffic in these drugs without interfering with their legitimate use by physicians and others. As the bill passed the House in June, 1913, it exempted from the operation of the law the dispensing or distribution of habit-forming drugs by physicians, provided the physician in each case was personally attendant on such patient. This exemption was modified in the Senate to require that the physician should have been employed for the particular patient receiving such drug and that the drug should be dispensed in good faith. The bill as agreed on by the conference committee and as finally passed exempts the dispensing or distribution by physicians of drugs containing opium or coca leaves or any of their derivatives, provided the physician keeps a record of all such drugs dispensed or distributed, showing the amount dispensed, the date, the name and the address of the patient. If, however, the physician is in personal attendance on the patient, such a record is unnecessary. Physicians and all others buying drug preparations containing opium or cocain must order them on forms to be issued by the Commission of Internal Revenue. But physicians' prescriptions are specifically exempt. As has been frequently pointed out, it is not in any sense a regulatory measure, and the amount of good that it will or can accomplish will depend entirely on the local police regulations and the methods adopted by states and cities to enforce such regulations. But after years of long, patient effort and many revisions, the bill as passed is probably the best that can be formulated under existing conditions. A complete abstract of the bill will appear in a later issue.

UNAPPRECIATED FEATURES OF THE SCHOOL LUNCH MOVEMENT

School lunches have become established in a large number of our cities, and a defense for their institution is now unnecessary. The maintenance of such a service is no longer defended solely on the basis of the needs of the poorer classes, but is encouraged in ways to avert the criticism that the school lunch leads to pauperizing and to the neglect of maternal responsibility in the home. The unquestioned benefits of a well-chosen warm lunch, usually supplied at the cost of the materials and service, have impressed both teachers and parents so that even the well-to-do commend and approve this latest innovation in the routine of the school day. As a rule, the school lunch room provides better food than the street vender. In most places the foods are chosen by persons trained in the field of dietetics, and the variety of dietary articles offered at one cent a portion is frequently quite impressive. It includes soups, salads, sandwiches, fruits, puddings and other dishes. The New York School Lunch Committee, in cooperation with the Bureau of Welfare of School Children of the Association for Improving the Condition of the Poor, for example, has maintained a service available to over 24,000 children in seventeen public schools situated in districts in which the need of such service is pressing. The registration has run as high as 2,353. In addition to this noon warm lunch service, the committee has operated a special 3-cent warm lunch of milk and crackers at 10 a. m. for anemic, ungraded and crippled classes. It begins to appear that the school lunch movement has engendered certain features which promise to contribute to the general welfare in a direction almost as important as that of the proper nourishment of the body. Educational and social possibilities, at first unforeseen, are being brought to notice.[1] The children of the well-to-do parents and the children of the poor have learned "to sit quietly as one family, to talk pleasantly with each other, to eat their food properly; and many acts of courtesy and generosity have been encouraged." The appeal which the school lunches have made has not infrequently been manifested by mothers who have had their interest in respect to special foods and dietary procedures aroused. Thus the school lunch scheme has fostered educational and social as well as economic purposes.

ACTIVITY OF DIGESTIVE FERMENT PREPARATIONS

A recent bulletin of the Bureau of Chemistry emphasizes anew the importance of determining exactly the activity of digestive enzymes and ferments. The great difficulty with these preparations is that they do not keep well, that while active at first, many, after a time, lose their digestive activity. Examination of certain preparations supposed to contain definite enzymes or ferments showed that in reality they contained little, if any, of these agents. Other investigations showed that the manufacturers had employed the proper quantities of pepsin, pancreatin, diastase or similar enzymes, but no attempt had been made to determine their activity. On the other hand, disregarding scientific evidence as to the proper medium or combination of the enzymes, pepsin and trypsin, which tend to negative each other, have been combined; pepsin has been used in alkaline mediums, which destroy its activity, and trypsin has been combined with acid substances not suited to it. Further errors have arisen through overheating enzymes or through issuing them in strong alcoholic solutions, lessening their effectiveness. Manufacturers are warned by the Department of Agriculture, through the Bureau of Chemistry, that combinations claiming to contain digestive enzymes must be active when sold. If preparations tend to deteriorate in a short time, each lot should be dated and not sold after the period when they become inactive. While every manufacturer must be considered innocent until proved guilty and ignorant until proved knowing, it is a matter of knowledge that many manufacturers have marketed their various digestive mixtures with full appreciation of their worthlessness. The Council on Pharmacy and Chemistry nearly seven years ago called attention[1] to the various digestive impossibilities on the market. Practically all of these are still sold. To sell a sick patient a mass of inert material which he believes to be active is not only perpetration of a fraud on the patient, but does gross injury to the physician who prescribes for him and endangers still further the patient's health. It is to be hoped that the government will adopt measures that will prevent the sale of such useless and scientifically absurd combinations.

THE MILK OF DIFFERENT BREEDS OF COWS

Among the various associations of breeders of milk cattle there is a lively competition in medical advertising literature for recognition of the superiority of the type of animal in which each happens to be primarily interested in either a commercial or a scientific way. Many physicians who read the announcements of the different groups of breeders have doubtless asked themselves whether the reputed claims of unlike composition for the milk of the various breeds of cattle concerned are in reality sufficiently distinctive to merit serious recognition from a scientific or practical point of view. It is, of course, widely recognized that types of dairy cattle which give a large amount of milk commonly furnish a product less rich in solids and particularly in the cream components. In this respect the milk from cows of the Jersey and Guernsey types departs noticeably from the Holstein variety; but inasmuch as it is believed, with some justification, that the composition of milk is more or less influenced by the period of lactation and the season of the year — that cows far along in lactation give richer milk than just after calving — one might well assume that incidental factors of this sort may easily counterbalance the inequalities of composition attributable to the differing types of cattle. During the past few years the laboratory of food and drug inspection of the Massachusetts State Board of Health has made extensive analyses of hundreds of samples of milk from Jersey, Guernsey, Ayrshire, Dutch Belt and Holstein cows, as well as from cross-bred or so-called grade cows.[1] The valuable data thus obtained under controlled conditions make it clear that variations in the composition of milk are due primarily to the breed, and to a less extent to the season of the year and the time since calving. The least variable milk constituents are the lactose and the mineral ingredients, both of which are therefore of value in detecting added water. Incidentally the fact is borne out, contrary to popular opinion, that milk obtained in summer under current conditions is, if anything, somewhat inferior in quality to that obtained in winter.[2]

THE SYSTOLIC DISCHARGE OF THE HUMAN HEART

The systolic discharge of blood from the heart and particularly the left ventricle, in man, is a factor of no small importance in the workings of the organism. The ability of the blood to distribute oxygen and thus permit the exhibition of energy under most favorable conditions, depends on its distribution by the cardiac muscle, and its oxygen-carrying capacity as expressed in its content of hemoglobin. The so-called tidal volume of the heart has never been measured with extreme accuracy. By estimations of what they term the "oxygen pulse," that is, the amount of oxygen consumed by the body from the blood of one systolic discharge of the heart, Henderson and Prince[3] have attempted to solve the problem of the magnitude of the discharge. The value of the "oxygen pulse" was calculated by dividing the amount of oxygen absorbed by the individual per minute by the number of heart-beats in the minute. From the data obtained for this factor under a variety of conditions causing various rates of

[1] Liquid Combinations Containing Pepsin and Pancreatin, The Journal, Feb. 2, 1907, p. 434. The Digestive Impossibilities, The Journal, Feb. 9, 1907, p. 533.

---

[1] Lythgoe, H. C.: The Composition of Milk as Shown by Analyses of Samples of Known Purity Made by the Massachusetts State Board of Health, Jour. Indust. and Eng. Chem., 1914, vi, 899.

[2] Inasmuch as the statistics may be of interest to physicians we append some of the average figures reported by Lythgoe:

	Solids Per Cent.	Fat Per Cent.	Protein Per Cent.
Jersey	14.7	5.6	3.4
Guernsey	14.6	5.2	3.7
Ayrshire	12.6	4.0	3.0
Dutch Belt	12.1	3.5	2.9
Holstein	11.7	3.4	2.9
Herd milk	12.8	4.0	3.3

[3] Henderson, Y., and Prince, A. L.: The Oxygen Pulse and the Systolic Discharge, Am. Jour. Physiol., 1914, xxxv, 106.

heart-beat, Henderson and Prince infer that the systolic discharge of the left ventricle of a well-developed man working hard and with a pulse-rate of 140 per minute is not less than 100 c.c. (3⅓ ounces) of blood. At slow rates of the heart-beat the systolic discharge is probably 150 c.c. (5 ounces) or more. In men of poor physique it is believed to be probably not more than two-thirds as much. The tidal volume of the whole human heart, that is, its change in size during the complete cardiac cycle, might accordingly amount to 400 or even 500 c.c. (16½ ounces). Such figures are considerably larger than those suggested by previous workers and are about twice as large as the values adopted in some of the current writings. The question promptly suggests itself whether the pericardial sac is actually large enough to allow the heart to make strokes of the magnitude here indicated. Henderson and Prince[2] have made direct measurements of the pericardial capacity in man. Their figures vary quite widely, as might be expected, with the size and general physique of the individual, and range from about 350 to 700 c.c. (23 ounces). A comparison of the pericardial volumes and the maximum possible systolic discharges permitted by them show that the pericardial sac in man is large enough to allow a systolic discharge considerably greater than it may be reasonably supposed that the heart will ever make. It may interest the members of the Association to know that the investigations here reviewed were carried out in the laboratories of the Yale Medical School, with the aid of a grant from the Committee on Scientific Research of the American Medical Association.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ALABAMA

Personal.—The house of Dr. Henry A. Darby, Athens, was destroyed by fire, December 3.——Major Henry A. Page, M.C., U. S. Army, has been appointed inspector-instructor in the medical department of the National Guard of Alabama and of five other states.

Tuberculosis Sanatorium Incorporated.—The Mobile City and County Sanatorium Company filed incorporation papers, December 3, the object being stated as the operation of a sanatorium or open-air camp in Mobile County for the treatment of tuberculosis. The organization has no capital stock, and the trustees incorporated are: Drs. Daniel T. McCall and Harry T. Inge, and Messrs. A. D. Block, Joseph D. Andrews and R. L. Waddle.

Extension of Mine-Rescue Station at Birmingham.—An extension of the mine-rescue station is needed at Birmingham, according to the report of Director Holmes of the Bureau of Mines, and recommendation to that effect has been made by the director in his annual report. He also recommends that living quarters be provided for the foreman in charge of the station in order that he may be on duty day and night. Birmingham is situated in a large and important mining district.

CONNECTICUT

Personal.—Dr. Simon R. Klein, formerly professor of histology and embryology in Fordham University School of Medicine, New York City, has been appointed pathologist of the Norwich State Hospital for the Insane.

GEORGIA

Personal.—Dr. William L. Funkhouser, Rome, has been elected medical director of the Cherokee Life Insurance Company, succeeding Dr. William W. Mangum, deceased.——Dr. Herbert E. Truax, Atlanta, has started for France for duty with the Red Cross.——Dr. R. S. O'Neal, Bronwood, has been appointed chairman of the Health Board of Terrell County.

Decrease in Infectious Diseases in Atlanta Attributed to School Inspection.—Dr. Willard E. Quillian, president of the Atlanta Board of Health, in a recent lecture, stated that there had been a notable improvement in the general health of the city through the suppression of infectious diseases. One year ago there were 350 diphtheria signs posted in Atlanta. At present there is only one. One year ago there were many cases of scarlet fever, to-day there are only four, and these are very mild. School inspection, he considered, had been a great aid in locating and checking the progress of disease.

ILLINOIS

Hospital Notes.—Frank M. Elliott, president of the Evanston Hospital Association, after nineteen years of service, has resigned on account of ill health.——The Compton Hospital was reopened December 3. It is now under the management of Dr. Clarence G. Pool.

Aim of State Tuberculosis Association.—The Illinois State Association for the Prevention of Tuberculosis and the other antituberculosis associations of the state are endeavoring this year to realize sufficient funds from the sale of Red Cross seals to pay for the services of a nurse in each community in the state.

Personal.—Dr. William P. Sherman, Aurora, was operated on for appendicitis, December 9.——Dr. J. Lenne Aleshire, Plainville, was painfully injured in a collision between his automobile and a street car in Quincy, December 4.——Dr. Albert N. Mueller has been appointed city physician of Rock Island, vice Dr. George G. Craig, resigned.

Unpaid State Health Board Recommended.—The Legislative Efficiency Committee, in its report on the administrative system of Illinois which appeared December 7, makes the following recommendations: The reorganization of the various health agencies into a state health department to be under the direction of a salaried health commissioner; an unpaid state health board of five officers to be appointed by the governor; the state health department to have supervision over the examination and licensing of physicians, pharmacists, dentists and nurses, and the regulation of those organizations which carry on other professions and trades for the protection of public health; a small board or committee to be provided for each profession to arrange for examinations, issue licenses and to revoke same for cause; the clerical and administrative work in connection with such examinations to be handled through one office and the action of the examining boards in revoking licenses, to be subject to review by the State Board of Health. The board of barbers' examiners to be abolished and the power of sanitary control over barbers to be exercised by the health department; the law for the collection of vital statistics to be made more effective; the pharmacy law to be revised; the cold storage of food products to be regulated and a state sanitary code to be enacted.

Chicago

Medicine Samples Not to Be Distributed.—The chief of police, on December 8, issued instructions for the arrest of any one distributing sample packages of medicine.

Zones of Quiet.—A resolution indorsing a petition before the city council to establish zones of quiet around hospitals, was adopted at a meeting of the council of the Chicago Medical Society, December 8.

Nurses' Association Needs Funds.—The Visiting Nurses' Association has issued an especial appeal for funds and announces that if the general public does not come to its aid many of its patients among the sick poor of the city will die from lack of nursing care.

Phone Exchange for Physicians.—A special phone exchange for physicians was advocated at a meeting of the council of the Chicago Medical Association, December 8. Drs. Willis O. Nance, Milton H. Mack and Albert W. Seidel were appointed a committee to urge the plan on the city council.

Health Conferences.—In connection with the Public Health Exhib [illegible] the City Club [illegible] conferences have been

---

2. Henderson, Y. and Prince, A. L.: The Systolic Discharge and the Pericardial Volume, Am. Jour. Physiol., 1914, xxxv. 116.

held on the following subjects: On December 4, "Food" was the topic for discussion. Prof. A. J. Carlson presided and the speakers were Dr. Carl Alsberg, chief of the Bureau of Chemistry, Washington, D. C.; Prof. John H. Long of Northwestern University and Dr. John L. White of the Chicago Municipal Laboratory. "Environmental Conditions" were considered at the evening session of December 7, and the noon session of December 8. The chairman at the first session was Prof. James H. Tuft, and addresses were made by Prof. C. E. A. Winslow of the New York State Board of Health; Miss Sophonisba Breckenridge of the Chicago School of Civics and Philanthropy, and Chief Sanitary Inspector Charles B. Ball of the Chicago Department of Health. Mr. Oscar F. Nelson, chief of the State Factory Inspection Department, Chicago, was the chairman at the second meeting at which Professor Winslow spoke a second time, and Dr. Alice Hamilton of the United States Bureau of Labor Statistics, delivered an address. The session of December 10 was devoted to "Infant Welfare." Mr. Lucius Teter, president of the Chicago Infant Welfare Society, was chairman, and addresses were made by Dr. Isaac A. Abt, Chicago; Passed Assistant Surgeon J. W. Schereschewsky, U. S. P. H. S., and Dr. Frank S. Churchill, Chicago. The noon meeting of December 12, over which Mr. Allen B. Pond presided, took up the question of "Health Administration," the speakers being Dr. George B. Young, health commissioner of Chicago, and Dr. Henry B. Favill, Chicago.

KANSAS

Personal.—Dr. Leon Matassarin, Wichita, while alighting from a street car recently, fell breaking his left humerus. ——Dr. Noah Hayes, who has practiced in Seneca for more than thirty-five years, has disposed of his practice and will live in Lawrence.

Government Recognizes Kansas Vital Statistics.—As the result of the enforcement of the Kansas Vital Statistics Law passed in 1911, Kansas has been placed among the twenty-four states accepted by the government as authorities on records of vital statistics.

Exceptional Outbreak of Diphtheria Abating.—Dr. John J. Sippy, Topeka, epidemiologist of the board of health, reports that diphtheria, which had run an almost unprecedented course throughout the state during October, is now abating. The outbreak started in the southeastern part of the state, the first cases being reported at Galena and Pittsburg. The progress of the disease could be traced along the railroad lines. At one or two places where medical inspection of schools was not indulged in on account of expense, it was necessary later to close the schools at greater expense. The board of health exhausted its supply of diphtheria antitoxin several times during the outbreak.

MAINE

Personal.—Dr. LeRoi S. Syphers succeeded Dr. Loring S. Lombard, resigned, as a member of the Board of Health of South Portland.——Dr. Edouard M. Marquis, Old Town, has gone to France to offer his services to the American Ambulance in Paris.——Dr. Edwin W. Gehring, Portland, has been appointed a member of the State Board of Health, vice Dr. Charles D. Smith, Portland, resigned.

MARYLAND

Civic Club Formed.—A Physicians' Civic Club has been organized in Baltimore by Dr. William T. Watson, with an initial membership of twenty-five.

Against Vaccine Law.—Believing that the compulsory vaccine law is unjust and drastic, the Washington County commissioners, sitting as a board of health, have adopted a resolution recommending that the health officer and all others in authority discontinue the rigorous enforcement of this law, allowing all to use their own judgment in the matter.

Lectures Before University Medical Society.—Dr. Lewis Gregory Cole of Cornell University delivered two lectures before the University of Maryland Medical Society, December 3, on "Anatomy and Physiology of the Stomach and Duodenal Cap," and on "Negative and Positive Diagnosis of Organic Lesions of the Stomach and Duodenal Cap." In the afternoon Lieut-Col. Champe C. McCulloch, Jr., M.C., U. S. Army, delivered a lecture on "Beri Beri."

To Join State University.—The University of Maryland, the College of Physicians and Surgeons and the Maryland Medical College, with three other institutions of learning were created into a Maryland State University, December 11. St. John's College, at Annapolis, was the only one of seven institutions that did not formally affiliate with the university, but this question will be decided at the annual meeting of their board in January. The affiliation of these institutions was decided on at the last session of the general assembly, when a law to that effect was passed.

Personal.—Dr. Franklin P. Mall, Baltimore, professor of anatomy at Johns Hopkins Medical School, has been appointed head of the new department of embryology of the Carnegie Institution in Washington. It is not likely that Dr. Mall will sever his connection with the Johns Hopkins University to pursue his new work.——Dr. George H. Whipple, a member of the faculty of the Johns Hopkins Medical School, has been appointed a director of the George Williams Hooper Memorial Foundation for Medical Research in the University of California.——Dr. Veader N. Leonard of Baltimore, who left on the first Red Cross expedition, is on duty at a 300-bed war hospital at Paignton, Devonshire, England.

MASSACHUSETTS

Personal.—Drs. Henry M. Chase and Gilbert F. Day have been appointed assistant surgeons to the Peter Bent Brigham Hospital, Boston.——Dr. Francis D. Donoghue, Boston, has been appointed a medical expert to the Industrial Accident Board.

New Health Council.—The governor has nominated the following as the new health council: Prof. W. T. Sedgwick, Massachusetts Institute of Technology of Boston; Drs. Milton J. Rosenau and David Linn Edsall of Harvard Medical School; Prof. George Chandler Whipple, sanitary engineer and secretary of the administrative board of the School for Health Officers; Dr. William J. Gallivan, former chairman of the Boston Bureau of Child Hygiene, and Dr. Joseph E. Lamoureaux, Lowell, a member of the local Contagious Hospital Commission and school committee. This council will cooperate with Dr. Allan J. McLaughlin, the new head of the board.

MICHIGAN

Hospital Sought for Cheboygan.—At a meeting of the medical profession held in Cheboygan, November 24, Dr. Stanislas A. St. Armour and James H. McCall were appointed a committee to confer with the Visiting Nurses' Association as regards establishing a hospital in Cheboygan.

Free Clinic at Lansing.—The Ingham County Nurses' Association has established a free medical clinic at Lansing, which was opened December 4. The Ingham County Medical Society has been asked to give free medical service for this clinic, which has been opened in rooms adjoining those of the Associated Charities in the Prudden Building.

Personal.—Dr. Edgar A. Planck, Union, has been elected a member of the state senate.——Dr. Flemming Carrow, who left the University of Michigan three years ago to combine pleasure, profit and health in the fruit-growing industry of northern Michigan, has made a specialty and success of growing chestnuts on his farm near Traverse City.

MISSISSIPPI

Hospital Notes.—The work on a new hospital at Meridian, which Dr. James H. Rush is about to build, will begin before the end of the month. The building will contain ten private rooms and four wards, in addition to the necessary offices, operating rooms, etc.

Personal.—Dr. John H. Lynn has resigned as house surgeon of the State Charity Hospital, Vicksburg.——Dr. Walter H. Rowan, Jackson, chief sanitary officer of Mississippi, has started for Central America to take charge of a campaign for the International Sanitary Commission. The State Board of Health, at a meeting November 20, adopted resolutions voicing the regret and reluctance with which the board accepted Dr. Rowan's resignation, and bearing testimony to his honesty, competency and fidelity.——Dr. Willis Walley, Richton, has taken up his duties as chief sanitary inspector of the state.

NEW YORK

Health Lectures at Albany.—A series of lectures, under the auspices of the State Department of Health, has been begun at Albany Medical College. The lectures are delivered on Tuesdays at 5 o'clock.

Tuberculosis Hospital Opened.—The Homestead Sanatorium, the Tuberculosis Hospital for Saratoga County, was opened December 5. The site for the hospital was donated to the county by Gen. Horace W. Carpentier in 1902.

Small-Pox in Hospital.—Four cases of small-pox have appeared among the patients of the Metropolitan Life Insurance Company's Hospital at Mt. McGregor, near Glens Falls. Everyone in the hospital and its vicinity has been vaccinated.

Dispensary Needs Funds.—An appeal to the public has been made by the president and board of trustees of the Syracuse Free Dispensary for $5,500 required to meet the expenses of the institution until Oct. 1, 1915. During the last six months 8,723 treatments were given as compared with 6,198 treatments during the same period last year.

Plans for Public Health Education.—The State Department of Health, in extending its work in public health education, has planned, in addition to the pamphlets furnished to the schools, to prepare a considerable number of compact exhibits, consisting of a series of striking charts to be circulated throughout the schools of the state. In order to reach rural districts where the installation of the regular exhibits would be too expensive it has also planned to send out a railroad exhibit car with lectures and moving pictures connected with it, similar to the exhibits being used so successfully in California and Louisiana.

New York City

Personal.—Dr. and Mrs. William A. Griffith, Brooklyn, have sailed for San Juan, P. R.——Dr. and Mrs. Robert F. Weir have sailed for Nassau and Guantanamo, Cuba.

Bill to Abolish Coroner's Office.—The investigation of the coroner's office in this city, which has been conducted for several weeks, is nearing an end. Commissioner Wallenstein, who has been conducting the examination, announces that sufficient evidence has been collected to demonstrate the abuses of the office, and to form a basis for a bill which will be presented before the legislature at the coming session. It is purposed to substitute the system in operation in Boston.

Subway Crowding and the Public Health.—Health Commissioner Goldwater recently sent a letter to the public service commission asking that it take official notice of the overcrowding on the elevated and subway trains since it was his belief that such overcrowding greatly promoted the spread of infection by the "droplet method." To this communication the chairman of the public service commission has made reply showing that the public service commission has expended a large amount of money to prevent transportation congestion, that it has not jurisdiction over health matters, and that it is within the power of the health department to prevent the practices complained of, namely, the coughing and sneezing.

NORTH CAROLINA

New Medical Association Organized.—The Winston-Salem Medical Association was organized recently with an initial membership of nineteen.

County Needs Hospital.—Davidson County is in need of a hospital. The fraternal organizations of Lexington have contributed $5,000 toward the building and stock subscriptions are now being solicited throughout the county.

District Society Meeting.—The Eight District Medical Society held its semi-annual meeting at Winston-Salem, December 1: Dr. Joseph W. Ring, Elkin, was elected president, and Dr. William M. Jones, Jr., Greenboro, was reelected secretary. It was decided to hold the spring meeting of the organization at Elkin.

OKLAHOMA

County Society Organized.—Grant County Medical Society was organized at Medford, November 24, with an initial membership of twelve, and the following officers were elected: president, Dr. Samuel A. Lively, Wakita; vice-president, Dr. Harry A. Stalker, Pond Creek; secretary-treasurer, Dr. Chester H. Lockwood, Medford.

Unprecedented Prevalence of Diphtheria.—According to reports received by Dr. John C. Mahr, Shawnee, state commissioner of health, diphtheria is more prevalent throughout the state now than at any time since Oklahoma was admitted to the Union seven years ago. There is scarcely a county in the state entirely free. Rigid quarantine and general distribution of antitoxin have enabled the authorities to get the situation well in hand, and the outbreak will probably be checked soon.

Personal.—Dr. Thomas J. Jackson, Marsden, who has been seriously ill with septicemia, has recovered.——Dr. John L. Plumbee, Poteau, who fractured his arm and sustained other painful injuries in a runaway accident a short time ago, has recovered.——Dr. Percy A. Smithe, Enid, has sailed to join the Red Cross service in Austria.——Dr. Walter H. McKenzie, Enid, who has been seriously ill, is reported to be improving.——Dr. Surl E. Williams, Hydro, while feeding his team late at night, November 27, fell from the hay loft with a lantern in his hand, setting fire to the hay. The barn was destroyed and the team burned to death, and Dr. Williams suffered a fracture of the hip and several burns.——Dr. William C. Whittenberg, Stillwater, has purchased the Buffalo Park Sanitarium, Pawnee, and the institution will be opened about January 21 for the reception of patients.

OREGON

Personal.—Dr. and Mrs. Walter F. Williamson, Portland, have returned from abroad.——Dr. John Griswold, Helix, is reported to be seriously ill.

Trachoma on the Umatilla Reservation.—It is reported that government physicians find trachoma prevalent among the Indians of the Umatilla reservation, all ages being affected but the young being the greatest sufferers.

New Medical Society.—Klamath County Medical Society, the first medical organization in any county of southern Oregon east of the Cascades, was organized November 14, at Klamath Falls, with an initial membership of twelve. Dr. Lawson L. Truax, Klamath Falls, was elected president; Dr. John L. Harris, Bonanza, vice-president, and Dr. Floyd M. White, Klamath Falls, secretary-treasurer.

PENNSYLVANIA

Small-Pox Epidemic.—Jamestown, a small village near Greenville, has been placed under quarantine by the State Board of Health. Twenty-seven cases of small-pox have been reported.

Outbreak of Diphtheria in Allentown.—An outbreak of diphtheria (upward of fifty cases) in Allentown during the latter part of November, necessitated calling in the aid of the State Health Department. Investigation showed that in this instance the schools were not centers of infection, most cases being those of adults and children under 5. Carelessness in observing the modified quarantine rules was regarded as the cause of the spread.

Alumni Clinic Day at Erie.—The first annual meeting of the Northwestern Pennsylvania Chapter of Jefferson Medical College Association was held at Erie, November 14. During the entire day and evening, scientific and social meetings and clinics were held. A business meeting of the chapter was called for the afternoon at which the permanent organization was effected with the following officers: president, Dr. John W. Wright; vice-president, Dr. Frank A. Walsh; secretary, Dr. Harrison A. Dunn, and treasurer, Dr. Claude Weston Page, all of Erie. The membership of the chapter includes all eligible Jefferson graduates who are residents of the counties of Crawford, Erie, Forest, McKean, Mercer, Venango and Warren.

Personal.—Dr. Robert W. Ramsey, Chambersburg, is reported to be seriously ill at his home.——Dr. Albert C. Lamade, Williamsport, was operated on for appendicitis in the German Hospital, December 1, and is reported to be doing well.——After fifteen years' service as a member and president of the Board of Health of Norristown, Dr. Alfred H. Read resigned December 1, and Dr. Willis R. Roberts was appointed his successor.——Dr. Theodore L. Hazlett, Pittsburgh, has been appointed an assistant surgeon in the third Russian Red Cross Unit to sail for Europe this month.——Dr. Johnston McLanahan, Chambersburg, who has been seriously ill with gastritis, is reported to be convalescent.——Dr. William McKenzie, Conshohocken, was seriously injured in a collision between his automobile and a trolley car, recently.——Dr. Benjamin J. Millard, Mount Carmel, while cranking his automobile, fractured his left hip.

Philadelphia

Cattle Quarantine Still in City.—A new order lifting the foot-and-mouth disease from fifteen different counties, and explaining the conditions under which cattle may be imported was issued December 11, by the state live stock and sanitary commission. Philadelphia County is still under ban.

Schools to Teach Care of Babies.—At the suggestion of the Child Federation, the Board of Public Education has established a course for little mothers in the seventh and eighth grades of the public schools. There are classes of instruction now operating in sixteen and seventeen schools under the Child Federation volunteer corps of teachers, and the latest development is a series of lectures in the Stock Exchange Building by Dr. Howard Childs Carpenter, instructing the teachers.

Discuss Hospital Plans.—Plans for the new Philadelphia General Hospital were discussed at a subscription luncheon given by the City Club to representatives of city councils, the County Medical Society and the Civic Club, December 12. Dr. Richard H. Harte of the department of health and charities outlined the proposed plan for spending one million dollars a year during the next five years for the erection of an entirely new group of buildings on the present site of the Philadelphia Hospital. Addresses were made by Dr. David Riesman, a member of the committee on rehabilitation of the hospital, and Dr. William D. Robinson, president of the County Medical Society.

Personal.—Dr. Thomas McCrae has been made consulting physician to the Girard College.——Dr. William S. Newcomet has been appointed radiotherapist to the Jefferson Hospital. ——Dr. George S. Crampton has been elected attending surgeon to the eye department of the Pennsylvania Hospital, vice Dr. Peter N. K. Schwenk, who resigned November 30, after twenty-three years of service. Formal ceremonies were held in honor of Dr. Schwenk at which he was presented with a silver loving cup by members of his staff and was also given flowers by the social service department and school nurses, and numerous tokens of esteem from other persons connected with the hospital.

SOUTH CAROLINA

Personal.—Dr. W. Thad. Hunt, Townville, is reported to be critically ill with nephritis in the Anderson County Hospital.——Dr. W. R. Bethea, who has been seriously ill with pneumonia at the Florence Infirmary, is reported to be improving.

New Society Organized.—Physicians of Calhoun County met at St. Matthews December 3, and organized the Calhoun County Medical Society electing the following officers: president, Dr. Lucius B. Bates, St. Matthews; vice-president, Dr. Asa P. Trawick, Cameron; secretary-treasurer, Dr. Thomas H. Symmes, Jr., St. Matthews.

Society Indorses Health Officer.—The Greenville County Medical Society adopted resolutions recently indorsing the work of the County Board of Health and of Dr. S. J. Taylor, the county health officer, requesting the county delegation to appropriate at least $3,000 for the work of the board of health for the coming year and appointing a committee of three to meet the county delegation and discuss the health questions involved.

District Physicians Meet.—The annual meeting of the Fourth District Medical Society was held in Seneca, November 24, and the following officers were elected: President, Dr. Joseph S. Stribling, Seneca; vice-president, Dr. Lawrence G. Clayton, Central; treasurer, Dr. James R. Young, Anderson. Easley was selected as the next place of meeting and the date of the meeting was changed from the second Tuesday in November to the fourth Tuesday in September.

VIRGINIA

New Organization of Colored Physicians.—The Hippocratic Medical Academy was organized at Roanoke, November 3, with the following officers: president, Dr. George E. Moore; secretary, Dr. A. W. Harris, Jr.——Magic City Medical Society at Roanoke: president, Dr. S. F. William; secretary, Dr. E. D. Downing.

Alumni Organized.—The Medical Alumni of the University of Virginia met in Richmond, November 11, and organized an alumni association, electing Dr. Hugh H. Young, Baltimore, president; Dr. Richard H. Whitehead, University, Va., vice-president, and Dr. Thomas V. Williamson, Norfolk, secretary-treasurer.

Monument to Confederate Surgeon-General.—The Association of Medical Officers of the Army and Navy of the Confederacy has planned a beautiful memorial to be erected over the grave of Dr. Samuel Preston Moore, Surgeon-General of the Confederate Army, who is buried at Hollywood Cemetery, Richmond. Other associations are cooperating in the erection of this memorial.

Personal.—Dr. James Allison Hodges, Richmond, has been elected president of the North Carolina Society of Richmond. ——Dr. John F. Ragland, Jr., Centralia, recently appointed coroner of Chesterfield County, who has been seriously ill with typhoid fever, is reported to be improving.——Dr. Stonewall J. Gill, Roanoke, underwent an operation at the Lewis-Gale Hospital in that city, November 25.——Dr. Kenneth B. Graves, bacteriologist of the State Board of Health, has been elected city bacteriologist of Richmond.

GENERAL

Conference on Child Labor.—The National Child Labor Committee has called a conference of all interested in the protection of children to meet in Washington, January 5 and 6, to emphasize the need of a federal child labor law and to discuss the question whether or not the federal government should intervene to prevent the conditions of child labor now prevailing in twenty-one states of the Union, where the employment of children under 14 years of age in mills and canneries is legal.

Fenger Memorial Fund.—The Directors of the Fenger Memorial Fund announce that $600 has been set aside for medical investigation in 1915. The money will be used to pay all or part of the salary of a worker, the work to be done under direction in an established institution, which will furnish the necessary facilities and supplies free of cost. It is desirable that the work undertaken should have a direct clinical bearing. Applications giving full particulars should be sent to Dr. Ludvig Hektoen, 629 South Wood Street, Chicago, before Jan. 15, 1915.

Sanitarians Elect Officers.—At the annual meeting of the American Public Health Association held in Jacksonville, Fla., December 1 to 4, the following officers were elected: president, Prof. William T. Sedgwick, Boston; vice-presidents, Drs. Charles J. C. O. Hastings, Toronto, Ont.; Juan Guiteras, Havana, Cuba, and Charles E. Terry, Jacksonville, Fla.; members of executive committee: Surgs. J. F. Anderson, U. S. P. H. S.; John H. Landis, Cincinnati, and Alfredo Dominguez, Havana, Cuba; secretary, Dr. S. M. Gunn, New York City, and treasurer, Dr. Lee K. Frankel, New York City. Honorary membership was conferred on Dr. Eduardo Liceaga, for many years president of the Bureau of Health of the City of Mexico. Rochester, N. Y., was selected as the place of meeting for 1915.

Hookworm Campaign in the Canal Zone.—The International Health Commission of the Rockefeller Foundation has established laboratory stations for the diagnosis and treatment of hookworm at Panama, La Chorrera and Bocas del Toro. The work was organized by Dr. L. W. Hackett of the commission, and according to the *Canal Record*, October 28, out of the first thousand men, women and children reporting at the La Chorrera laboratory more than 700 were found to be harboring hookworm. An effort is being made to induce every inhabitant of this village of 4,000 to submit to examination for hookworm, and circulars in simple language have been distributed and house-to-house visits and investigations have been made. Treatment is free, but not compulsory, although the work is carried on at the request and with the cooperation of the Panama government, and pressure may be brought to bear to make the campaign a thorough one. The establishment of laboratories in Panama is in pursuance of the plan of the International Health Commission for a world-wide campaign of health work in countries requesting the cooperation of the commission. Panama was one of the first countries to invite assistance. Great Britain has already solicited cooperation in behalf of her tropical possessions and a French and Dutch colonial service and an oriental service are also under consideration.

WAR NOTES

Dr. Crile Takes Charge of Division in American Ambulance at Paris.—Dr. DuBouchet, in charge of the American Ambulance at Neuilly, has placed at the disposal of Dr. G. W. Crile one division of the hospital, consisting of 150 beds. Other surgeons and nurses will also go from the Lakeside Hospital, Cleveland. The party, which will sail December 30, includes also Dr. Samuel J. Ledbetter, resident surgeon of the Lakeside Hospital; Miss Agatha Hodgins, chief anesthetist, and Miss Iva Davidson, operating-room nurse.

American Ambulance Surgeons Daring.—The American Ambulance Corps of Paris has done much daring work at the front, but so far there has been not a single casualty among the staff, although the life-saving work has been carried on close to the firing line. The British Ambulance Corps has not been so fortunate, as one ambulance near an American Ambulance car, was struck by a shell and demolished, its entire crew being killed or wounded.

Red Cross Work Changes.—The American National Red Cross, at its tenth annual meeting in Washington, December

9, readjusted its European war work. Hereafter, the society will not solicit contributions for non-combatants, but will limit its solicitations to funds for relieving the sick and wounded in the armies at war. It will transmit, however, non-combatants' relief funds to the European Red Cross organizations when the donor designates the country to which the funds are to be sent.

Aid for the Austrian Red Cross.—Dr. Adam P. Leighton informs us of the receipt of a letter from Dr. Oskar Frankl, editor of the *Gynäkologische Rundschau* of Vienna, regarding the work of the Austrian Red Cross. Dr. Frankl states that doctors have given up their accustomed clinical work and are now military surgeons in service of the Fatherland. As with other countries, the Red Cross is in need of funds. Anyone desiring to contribute for this cause may send their contributions direct to Dr. A. P. Leighton, 192 State Street, Portland, Maine, or Oskar Frankl, Franz Josefs-Kai 17, Wien, I., Austria.

More Clothing and Supplies Sent to Europe.—The American Red Cross shipped to Europe on December 13, 401 cases of hospital garments, hospital supplies, blankets, shawls and clothing for the women and children of the war zone.——To France were sent 89 cases of hospital garments, women's and children's, 9 cases of absorbent cotton, several cases of iodin and antiseptic tablets.——To the German Red Cross were sent 71 boxes containing hospital garments, women's and children's clothing, hospital linen and absorbent cotton and bandages.——To the Austro-Hungarian Red Cross were sent 71 cases of hospital garments and clothing for women and children, and 20 bales of absorbent cotton.——To Rotterdam, there were sent for the use of Belgian refugees in Holland, 94 cases of clothing for men, women and children, overcoats, 3,000 blankets and 1,400 shawls, and 65 cases containing nearly 4,000 blankets for the Belgian Relief Committee for Belgium.

Aid to Belgian Physicians and Surgeons.—An appeal made by Sir Rickman J. Godlee of London, chairman of the committee organized in Great Britain in aid of Belgian physicians and surgeons, has resulted in the organization of an American committee which will accept subscriptions in money and surgical or pharmaceutical supplies and distribute them to the best of their ability among the Belgian sufferers. The appeal is accompanied by a contribution by Prof. C. Jacobs of the University of Brussels on "The Position of Belgian Doctors and Pharmacists" and a letter by Sir Gilbert Parker to the Chicago *Tribune*, both of which explain most clearly and vividly the needs of the Belgians.——Dr. Frank F. Simpson, 7048 Jenkins Arcade Building, Pittsburgh, has consented to act as treasurer to the American Relief Committee which consists of Drs. William L. Rodman, Philadelphia; Charles H. Mayo, Rochester, Minn.; John M. T. Finney, Baltimore; George H. Simmons, Chicago; Thomas L. Stedman, New York City; Edward W. Taylor, Boston; Franklin H. Martin, Chicago, and Howard Canning Taylor, New York. Contributions should be sent to the treasurer, Dr. F. F. Simpson.

Work in American Ambulance at Paris.—Dr. Blake, in a letter to an American correspondent states:

> "In view of the great number of surgeons who are applying and who are coming over, I think it would be wise for you to give out a statement to be published throughout the medical press that the Ambulance of the American Hospital in Paris is in reality a hospital of between four and five hundred beds, situated in the environs of Paris at Neuilly, that the staff at present is full, and that only from time to time new men will be needed to fill the vacancies by men leaving. On account of the fact that nearly all the patients are French, and that histories of the cases in French are required by the government, it is highly desirable that applicants should be able to speak French.
>
> Further, that extensions to the work of the Hospital carried out in other places than the neighborhood of Paris for the immediate present, are being manned by complete units leaving America as such, and consequently their personnel is to be recruited before leaving.
>
> Further, in order that applicants may get information more readily, Dr. Gibson and yourself have been requested by the Staff of the American Ambulance to act as a Committee to whom applications should be made."

In accordance with the above request made in a letter from Dr. Joseph A. Blake to Dr. Hugh Auchincloss, dated Paris, Nov. 14, 1914, applications for service of any kind—doctor, nurse, orderly, ambulance driver—in the American Ambulance or its units will be received by Dr. Charles L. Gibson and Dr. Hugh Auchincloss, acting as a committee appointed by the medical board of the American Ambulance. All applications should be made out so as to cover fully, and in detail, all the information requested in the application form, which Dr. Hugh Auchincloss, 178 East Seventieth Street, New York City, will send to any one requesting it. Notices will then be sent directly to any applicant when, on hearing from the American Ambulance in Paris, it may be deemed by the committee that his or her services may be made use of. It should be remembered by all applicants that a passport is an absolute essential, if going abroad, and that the new regulations for securing one are much more stringent than formerly, and that a new form of application blank has been adopted by the government within the past month.

LONDON LETTER

London, Nov. 27, 1914.

The War

The uniformly septic condition of the wounds which have come under treatment in the hospitals, and the failure of the modern "aseptic" treatment, have caused a proposal to revert to the old antiseptic treatment. The latter is now in the ascendency. The importance of immediate disinfection of wounds is recognized and, following the example of the French, a small quantity of iodin is being supplied to each man to be used as soon as a wound is inflicted. Every effort is being made to preserve the health of the troops in the field, so far with complete success. We have had no cases whatever of cholera and few of typhoid. Divisional sanitary companies consisting of sanitary inspectors and men of the scavenging class are being prepared to be sent to the front. A sanitary committee which was sent out by the government has reported that nothing could exceed the sanitary accommodation of the actual trenches. With the advent of the frost there are some cases of frost bite, dysentery, rheumatism and pneumonia. It is remarkable that cases of illness are so few, considering that the men have often to stand ankle deep all night in slush. The motor ambulances are proving invaluable in the removal of the wounded from the field of battle, but the conditions of present-day warfare have rendered immediate succor difficult and often impossible. Horse ambulances are pushed forward during an engagement as near the firing line as is consistent with moderate safety, and the wounded are placed in them from the regimental aid posts behind the firing line. In the course of the protracted semisiege-like battles which are characteristic of this war, it is usually only under cover of darkness that it is possible for the wagons to approach the aid posts, and the collection of wounded is accordingly begun at dusk.

Having collected the wounded, the wagons are driven to the headquarters of the field ambulance, which may be two, three, or four miles in the rear; here the patients are fed on hot beef tea, soup, tea, milk or other sustaining food. Their wounds are redressed, if necessary, and operations of urgency undertaken. In some cases it may happen, as at the battle of the Aisne, that the headquarters of the field ambulance are so near to railroads that the wounded can be transferred straight to ambulance trains or to clearing hospitals in which they can await the arrival of such trains. But as a rule this is not the case; there is nearly always a gap of some miles separating the headquarters of the field ambulances and the nearest available point reached by ambulance trains. It is this gap which the motor ambulances are employed to bridge, and most excellently they do it. Before they appeared, all sorts of shifts were necessary. Whenever the troops advance (or retire) the field ambulances are required to advance (or retire) with them. It is essential, therefore, that the field ambulances should retain their patients for as short a time as possible, for it is obvious that they cannot move with the troops if they are encumbered with hundreds (or even scores) of wounded patients. Thus the motor ambulances, working rapidly backward and forward between the railhead and the field ambulances, achieve a double object: they ensure speedier and far more comfortable transit for the wounded to those places where their wounds can best be treated and healed, and they enable the field ambulances to retain their full mobility and so serve most efficiently the needs of the troops among whom further casualties may occur. The motor ambulances run so speedily up and down that the field ambulances are never allowed to get choked up with wounded, even after a big engagement. If the order comes to march before all the wounded have been taken away in the cars, all that is necessary is to send word to the latter that the patients are lying in a certain house or farm and to leave one or two orderlies behind to look after them until the motor ambulance arrives.

Casualties Among Army Surgeons

The heavy casualties among army surgeons continues. The list for the past week is one killed and five wounded.

In the present war their work is very dangerous. To succor the wounded where they fall they must travel long distances up and down a long front, exposing themselves to the enemy's fire. It is now beginning to be realized that the wounded are safer lying where they fall, provided some one will apply the first field dressing. To carry wounded men or allow slightly wounded to walk to the aid posts during an engagement exposes them to the grave risks of additional wounds and means losses among the medical personnel. It is better that wounded men, having received first aid, should lie until darkness enables them to be moved with safety.

Gas Gangrene

An important report has been made to the government on emphysematous gangrene (which, as previously stated, is rife among the wounded) by Sir Anthony Bowlby, consulting surgeon to the forces, and Dr. J. S. Rowlands, a bacteriologist. A bacillus was isolated which, when inoculated into a guinea-pig caused fatal gangrenous cellulitis. Examination of a culture at the Lister Institute by Dr. C. J. Martin and Dr. Arkwright inclined these observers to the view that the organism is identical with one that for some time was confused with that of malignant edema, known as the bacillus of Ghon and Sachs. This organism was originally obtained from a case of gangrene in the human subject. There are ten different organisms that have been isolated from cases of gas gangrene in man, all of which are closely allied and have the common characteristic of being anaerobic spore-bearers. From other cases in the clearing hospitals at the front several more organisms of this group have been isolated and have been sent to the Lister Institute for confirmatory diagnosis. A sample of earth from a trench was also examined. The inoculation of a few drops of water, in which this earth had been shaken up, into a guinea-pig killed the animal in eighteen hours. Post mortem a similar gangrenous cellulitis was found. The animal was also found, like the guinea-pig inoculated from the gangrenous culture, to be infected throughout with a spore-bearing anaerobic organism belonging to the same group. It is reasonable to conclude, therefore, that the gangrene found among our wounded soldiers is directly due to infection introduced at the time of the wound, and this is especially likely to occur if muddy clothing has been carried in by the projectile or if earth has been carried in the explosion. It is solely due to infection from the soil and is in no way related to sloughing phagedena, or so-called "hospital gangrene." The onset is characterized by swelling of the injured part, and the gangrene seems especially liable to occur in connection with that swelling of a limb which is due to extravasation of blood in the subcutaneous tissues and intermuscular planes. It seems that interference with the circulation either by extravasation of blood or by tight bandages has a marked influence. In the early stages the patient complains of severe pain, which is perhaps due to tension, the result of the swelling, but in the later stages the affected area becomes completely numbed and insensitive. The edges of the wound are generally ragged and sloughy, and a considerable quantity of blood-stained serum constantly exudes and soaks the dressings. This discharge emits a characteristic and most offensive odor, which is so marked as to be almost diagnostic. The skin, if not previously discolored by extravasated blood, assumes a dark purplish or slate-colored hue. In the vicinity of the wound it changes subsequently to a greener color. The swelling extends coincidently with the change of color, and a few hours later the skin becomes nearly black, and finally forms a black, leathery slough. Beyond the area of discoloration the limb is swollen with gas and fluid exudation, and an emphysematous crackling can be elicited on pressure with the hand. This may spread to a distance of as much as a foot above and below the actually gangrenous area, and so rapid is the extension of the gangrene that the whole of the lower extremity may be completely mortified before the end of the third day after the infliction of the wound. The following practical conclusions are drawn:

1. All tight bandages, and especially those applied at the first field dressing, should be avoided. Shell wounds are so often followed by so much interstitial hemorrhage that the part swells and the bandage rapidly becomes tighter and interferes with the circulation. Consequently, many bandages have to be cut within a few hours of their application.
2. In many cases it is necessary to relieve the tension by incisions and drainage, and the opportunity should be taken to wash the wounds thoroughly with an antiseptic. Hydrogen peroxid is one of the best. Great care should be taken to remove portions of clothing, as these contain the infective agent. Shattered fragments of bone and pieces of shell or gravel should be taken out.
3. Amputation may often be successfully performed through tissues made emphysematous by gas but not yet gangrenous.
4. The group of anaerobes causing gangrene are spore-bearers, and spores (especially of this group of anaerobes) are difficult to kill by any antiseptic solution or even by boiling. Consequently, in order to sterilize instruments and other things that have been infected, other measures are required. These are: destruction of blankets and clothing soaked by the discharge, heating in an autoclave at a temperature of 120 C. (248 F.), or boiling for an hour in a solution of phenol (carbolic acid) 1:20, or compound solution of cresol, 1:10.
5. Where possible it is advisable to isolate patients under treatment in hospitals, and this is all the more necessary on account of the bad smell which is inseparable from the condition.

Effect of the War on the Medical Profession

At the General Medical Council (the body of which controls examinations and registration of physicians) the president, Sir Donald MacAlister, in his address referred to communications which had been received from several licensing authorities as to the propriety of modifying or suspending some of the existing regulations in the case of students whose regular course of study might be interrupted by military service. He said it was the duty of the council to maintain such a standard of proficiency as would guarantee the possession by candidates of the knowledge and skill requisite for the practice of the profession. Multitudes of their professional brethren had nobly offered themselves for service with the troops at home and abroad; many had already laid down their lives in the performance of that humane duty. The toll of war was not yet complete. They must face the certainty that before long the ranks of the profession would be sadly depleted. Ample reserves were necessary to supply the places of those who fell on the field of honor. Those reserves would be constituted by those whom they were *now* admitting to the status and privileges of registered physicians. They would best honor the memory of the fallen and safeguard the welfare of the forces and the people if they did all in their power to secure that the men who entered the profession were as fully and as efficiently trained as their predecessors. The need for efficient physicians in the field and at home was not less urgent than the need for efficient soldiers and sailors. He had felt it his duty to press this consideration on senior students who, though they had nearly completed their curriculum, were ready to forego the prospect of early qualification and to enroll themselves straightway in the combatant forces. It was currently reported that owing to the war the number of the students of all years enrolled for the present medical year was much below the average. If that were true, the risk of a serious shortage in the future supply of physicians would appear to be imminent.

PARIS LETTER

PARIS, Nov. 26, 1914.

School for Cripples

During the four months that the war has lasted, our hospitals have discharged numbers of crippled soldiers. What is going to become of these young men, some scarcely over 20? They cannot be abandoned to public charity. All means should be used to make them capable of practicing a trade. The mayor of Lyons, M. Edouard Herriot, reminds us that for a long time the Scandinavian countries have concerned themselves with the problem of the training of cripples. In 1872 the Danish philanthropist, Hans Knudsen, founded at Copenhagen his celebrated orthopedic policlinic, and institutions of the same kind have been opened at Helsingfors, Stockholm and Christiania. M. Herriot visited some months before the war, the training-school for cripples and victims of industrial accidents founded in Charleroi, Belgium, by the province of Hainaut in 1906 after the passing of the Belgian law on compensation for industrial accidents. The workshops of the school were directed by a physician whose duty it was to find out the suitable trade for each pupil when he enters. One might see, for example, a man who had lost both forearms enabled to make brushes by means of a special apparatus. One of the stumps was fitted with a mass of steel, serving as a hammer, the other with a leather pad furnished with a magnet for placing the nails. The school had its prothesis workshop where the physician's ingenuity was taxed by the most various problems. Seven sections were in regular operation: a school of shoemaking, a school of bookbinding, a school of harnessmaking, a school for the cutting and making of clothes, a school of basketmaking, a school for making matting and a school of bookkeeping. The instruction was both theoretical and practical. The cutting school in particular did most acceptable work. The institution could not supply the demands for work people. The basketmaking section also was overwhelmed with orders. Well-organized canteens nourished cheaply this little community of workers saved from want and idleness. Their intellectual development was the object of the same care as their physiologic reeducation. Since the present war renders some such measure urgent, the city of Lyons, which is particularly rich in scientific and industrial resources, has volunteered to found without delay, the first school for cripples in France.

An Appeal of the French Sanitary League

The object of the Ligue sanitaire française, whose president is Dr. Raphael Blanchard, professor of parasitology and of medical natural history at the Faculté de médecine de Paris, is to disseminate the principles of general hygiene. The league believes that under the present circumstances it has a special urgent task to fulfil. It is well known that after all wars the devastated regions are generally subjected to another scourge, that of epidemics (typhoid fever, choleriform infections, dysentery, etc.). To prevent this new calamity, the league has decided to send out a poster to the 6,000 communes affected by the German invasion indicating the most urgent hygienic precautions; for instance, against careless burial of bodies, pollution of springs and wells, and epidemic diseases with information about how they are spread and how they may be avoided. This notice will be posted in all communes. Moreover, wherever the mayors request it, public conferences will be held and it may be that antiseptics will be distributed free on request. The league appeals to all its friends to aid (1) by subscriptions of money, (2) by gifts of antiseptics, (3) by the loan of automobiles and (4) by any other methods. Donations may be addressed to the Secrétariat général de la Ligue sanitaire française, 72, rue de Rome, Paris.

Sanitary Postal Cards

The families of sick and wounded soldiers have complained very justly that they receive only much delayed and very insufficient information. The minister of war has endeavored to meet this complaint as far as possible. Hospitals have been ordered to furnish lists of names of the sick and wounded to be sent to relatives of patients. Moreover, a sanitary postal card has been devised which is to be sent to the families with the signature of the head physician at the time of the admission of the soldier to the hospital and thereafter each week as long as the patient remains. Unfortunately, the heads of too many hospitals of the territorial or reserve army are unfamiliar with military discipline and up to the present they have tended to regard these lists as tiresome administrative red tape which could, in any event, be postponed to a convenient season. Very precise and peremptory instructions have just been given by the minister of war so that this duty may no longer be shirked.

BERLIN LETTER

Berlin, Nov. 7, 1914.

Experiences of the Latest Military Surgery

In a hospital in northern France, where the army headquarters are also situated, the Leipsic surgeon, Professor Payr, delivered a lecture a few days ago on the experiences which he had so far had in the present campaign. He said that military surgery has to reckon with an especial difficulty because the injured are pressed on the surgeons in such numbers that the surgeons are not physically capable of meeting the demands on them. The surgeon in the field must, as has always been the principle of our German sanitary service, work as simply and surely as possible. He must dismiss the wounded that he does not keep under his care in such condition that they may be transported further without danger from any possible accident. In this case, the surgeon in the war lacks any self criticism of his results because he loses sight of his patients in the great majority of cases immediately. However, previous experiences have already given some definite guiding principles. Among them belongs, for instance, the principle that surgeons should not operate too early.

VARIOUS KINDS OF WOUNDS

The wounds differ according to the kind of projectile and according to its effect. They concern infantry bullets, shrapnel, pieces of grenade or shells. The modern French infantry bullet consists of comparatively soft materials and is easily deformed. This occasions the hook form in which it is generally found in the wound. Nothing can be said with reference to the shape of pieces of grenade and shells. Something quite new which has been introduced with this war is the flying arrow. With dramatic vivacity Payr described the first experience of our troops with this weapon. Above a column of marching infantry there appeared a hostile aviator. While it was noticed that he was throwing no bombs, a man suddenly cried out, "I am hit." Although surgical examination at first showed only an insignificant wound on the left shoulder, the patient bled to death under the hands of the surgeon. Necropsy showed that the arrow had pierced the upper fossa of the clavicle, the left lung, the diaphragm, the spleen, the thigh and the pelvis, and had made its exit from the body at the knee. The arrow was found in the trousers of the dead man. It was a pointed piece of steel with the strength of a pen holder, the posterior half of which had been hollowed out quadrangularly so that in falling the heavy point was always downward. A number of such arrows hang in a perforated board under the aeroplane from which they can immediately be released by the pressure of the foot of the aviator, so that a certain scattering and volley-like discharge is secured. At an elevation of 1,500 meters (about a mile), from which they are generally thrown they reach the earth with a final velocity of 200 meters per second, which corresponds to the velocity of one of the older rifle balls. In cases like that described, the effect was fatal, but wounds from the aeroplane arrows are rare.

In describing the injuries of tissues and organs, the lecturer showed that the blood-vessels are cut through by the modern infantry bullet with a smooth wound. The number of injuries to blood-vessels in this war is larger than has been anticipated. The muscle swells up after a few seconds until its counterpressure is great enough to hinder the further exit of blood from the open vessel. Moreover, the nerves have no longer time to yield to the infantry bullet but are smoothly cut across. As far as concerns the serious injuries of bone, it has been shown that shot wounds of the joints take a comparatively favorable course as the result of spongy consistency of the bones about the joints, while the long bones with their ivory-like hardness suffer severely at the distances with which we have to reckon with our far-carrying weapon, and are splintered at a distance of from 1,600 to 1,800 meters. In the internal organs the tendency of the bullet to cause rupture comes into account if, like the kidney and bladder, they are filled with fluid. A peculiar phenomenon is wound fright, a condition in which, even with a relatively slight wound, the wounded show a very serious appearance and a small pulse.

Wounds of the head are especially frequent in modern warfare as a result of the extensive employment of protecting trenches. These wounds may be divided into perforating, tangential and furrowed. The perforating wound is the milder one. A man could be shown who had received a shot transversely through the brain but who yet was able to answer any questions, although with some delay. Sometimes in such cases an abscess of the brain occurs in consequence of infection, but it is possible to reach this by operation, and the case is by no means hopeless. On the other hand, the tangential wound in which the bullet has ploughed an open furrow in the skull shows almost without exception a very severe wound which is dangerous on account of splinters of bone and infection. Here energetic operative interference is generally necessary and, if carried out at the right time, affords in many cases, even with deep wounds of the brain, the prospect of complete recovery. Wounds of the neck, in spite of the crowding of important vital organs in a small space, pursued an astonishingly favorable course in the majority of cases. In wounds of the larynx, tracheotomy was often performed at the field hospital on account of the danger of suffocation. Wounds of the thorax permit almost the best prognosis. Smooth penetrating wounds through both lungs were in many cases so little dangerous that the wounded could already be transported after from ten to fourteen days, even if they had coughed up blood for a couple of days. To be sure, in wounds of the heart and its auricles the progress of surgery, which has made it possible in times of peace to suture such wounds, can be applied only exceptionally in time of war. Wounds of the abdomen were characterized by the lecturer as a disputed territory. The South African War afforded the experience in contrast with former views that it is better not to undertake operative treatment on abdominal wounds immediately but to postpone it. Multiple perforations of the intestines pursued a favorable course if the wounded were allowed to remain quiet for a week without eating or drinking.

THE WORK OF MILITARY SURGERY

The entire work of military surgery consists in the first aid to the wounded, the final care of the wound and the after-treatment. The first aid consists chiefly in the stopping of hemorrhage. In reference to this, the lecturer remarked that the ligature of arteries had been found to be especially important in this war. The prevention of infection also belongs to the first aid. Brilliant results have been secured by the small bandage of germ-free gauze which the soldiers themselves apply in the field or which is applied by their comrades. The third task of first aid treatment is preparing the wounded for transportation. Here the strong cars introduced into the sanitary service do excellent work. The wounded man must be dismissed in such a condition that the surgeon is convinced that no further accident can happen to him on the journey. Broken bones must be fixed in plaster or with splints. The surgeon must in such cases often improvise his apparatus. Very good splints can be made from the limbs of trees and be covered with straw when no other material is at hand. In the final treatment of the wound, the principle has been adopted not to operate too hastily so that the aseptic healing which has already begun may not be interrupted. No importance is attributed in general to the removal of the bullet from the body unless it is necessary.

The shrapnel bullet often carries pieces of clothing into the depths of the wounds on account of the slight force with which it reaches its mark. In from 70 to 75 per cent. of cases, according to the experience in this war, shrapnel wounds resulted in suppuration. Also pieces of grenades with their ragged edges often carry foreign bodies into the flesh. Among the complications which may result, especially in artillery wounds, is the not very rare occurrence of tetanus. The attempt has been made to prevent this by the injection of tetanus serum. Also the injection of tetanus serum into the spinal canal, the nerve centers and the circulation has given successful results in the treatment of developed cases of this fearful disease. As a rule, the simple wounds of the soft parts by infantry bullets pursued a favorable course. In many cases those who had been struck by these bullets were fit for service in the field a week later. Wounds of the joint with infantry weapons pursue a favorable course if splints are applied at the right time. Wounds of the long bones are often much more serious from the distances with which we are concerned generally in this war. They are the crucial cases of our hospitals. It has been shown that delay in operation in these cases is often undesirable, but that an immediate free opening of the gunshot fracture is the proper treatment. Naturally, surgery of the present day, which has become eminently conservative, no longer takes the stand as shown by the distinguished Baron Larrey, chief surgeon of Napoleon I, who believed that he was giving the best help to the wounded if he amputated the wounded limbs. But it has been shown, on the other hand, that military surgery of the present day, in some rare cases, has probably become too sparing of amputation. Wounds of the skull as well as those of the neck and chest pursue a relatively favorable course, but the furrow-like wounds are dangerous. Bombs from aeroplanes are peculiar in their action. The wounded much oftener show burns from these than from the grenades and the splinters produce an especially sharp dagger-like wound canal. Payr closed with praise of the arrangements for moving the wounded, especially the luxuriously equipped hospital trains.

Berlin, Nov. 16, 1914.

The Number of Casualties

The lists of names published in the *Deutsche medizinische Wochenschrift* show that to date the German army medical corps has lost 287 members. Among them, 94 were killed on the field of battle, 12 have died, 90 have been wounded, 27 taken prisoners and 64 are missing, which probably means that they are prisoners. Undoubtedly the number of actual losses is still greater. The facts naturally become known slowly by the troops and are still more slow in reaching publication. It is especially to be regretted that, on the one hand, so many have fallen in the exercise of their professional work and, on the other hand, that so many physicians have been taken and are being held prisoners.

The Iron Cross for Physicians

In contrast with these sad features of the war, we must note that the number of decorations for gallantry in the field (the Iron Cross of the first and second class) awarded to German physicians is extraordinarily great. As is shown by the official communications, these are given not only in appreciation of exhausting and successful professional work but also as a recognition of bravery in the face of the enemy. Many physicians have for hours tended the wounded in the front ranks during a rain of bullets. Many have taken their charges out of hospitals which were exposed to a shower of the enemy's bullets, and were partly on fire. It is easily understood that many of our colleagues lost their lives in this way.

Death of Weismann

August Weismann, zoologist and biologist, died November 6 after a short illness, at the age of 81. He was one of the most distinguished German naturalists of the present period, and had taken first place among the investigators of the Darwinian theory of evolution. Originally he studied medicine. After passing his state examination, he was for a time an assistant at the medical clinic at Rostock. Then he went to foreign countries for further practical education, and his interest in zoology led him gradually to devote himself exclusively to this field. He became a pupil of Leuckart at Giessen and in 1863 he joined the faculty of Freiburg in zoology and comparative anatomy, and in spite of frequent honorable calls elsewhere he never left this university. Weismann devoted his scientific lifework almost exclusively to the grounding and further development of the theory of the evolution of species, and in this field again he preferably devoted himself to one of the most difficult and disputed biologic problems, that of heredity. Darwin had adopted as a temporary hypothesis for the explanation of the inheritance of peculiarities the theory of pangenesis, which in its basic principles goes back to Hippocrates. This theory teaches that from all parts of an organism material contributions pass into the juices of procreation so that the latter, to a certain extent, consist of a concentrated extract of the former. He assumed in this that a living organism had the power of transmitting to its progeny those peculiarities which it had acquired for the first time in the course of its individual existence. He regarded this as an essential factor in the further development of the characteristics of a species and the formation of new species.

The numerous difficulties which the Darwin theory of heredity had encountered led Weismann to more or less successful researches to remove its defects and particularly to secure comprehensible morphologic ideas of the manner in which the elements passing from the entire organism to the sexual cells are to be regarded as active. One of the most important results of these investigations is the theory developed by Weismann—in conjunction with Jäger, Galton and other investigators—of the continuity of the germ plasm. Whatever one may think of its explanatory value, this theory has been, at any rate, very fruitful and rich in results by the stimulus which it has exerted, not only on biology, but also on pathology, natural philosophy and other sciences.

On the basis of this theory, Weismann reaches an exactly opposite result to that of Darwin with regard to inheritance of acquired characters, since Darwin found no difficulty in assuming the possibility of extensive modification of the germ elements. In contrast with this, Weismann declared that the endogenous structure of the germ plasm, with which the function of heredity is connected, is unchangeable and stable. All those characters which the individual in the course of his life has acquired from external sources—changes of organs, diseases, deformities, etc.—cannot, according to Weismann, be transmitted to the offspring. In numerous publications Weismann expounded his theory, which provoked long discussions in the world of science, lasting even to the present time. He published in 1892 "Das Keimplasma, eine Theorie der Vererbung," and in 1902-1904, "Vorträge über die Deszendenztheorie." Of more popular interest are two inspiring productions "Ueber die Dauer des Lebens" (1882), and "Leben und Tod" (1884)—"Length of Life," and "Life and Death"—in which he sought to demonstrate that the length of life of individuals is the result of natural selection, a phenomenon of adaptation which has been produced by the advantage which it affords for the maintenance of the species.

August Weismann was not only a noted and thorough investigator but, what is not always associated with this, he was an excellent university teacher who enjoyed the highest regard of his hearers because of the wonderful clearness and distinctness of his address.

Marriages

Joseph Augustus Blake, M.D., to Mrs. Katherine Alexander Duer, both of New York City, in Paris, France, November 28.

Leroy Thomas Geer, M.D., Syracuse, N. Y., to Miss Adele May Spencer of Los Angeles, at Auburn, N. Y., November 13.

Leroy Francis Heimberger, M.D., Wei Hei Shien, China, to Miss Louisa Corbett of Chefoo, China, November 26.

Clarence Edward Burt, M.D., to Miss Anne Beatrice McCullough, both of New Bedford, Mass., November 25.

Wilbur Randolph Hurst, M.D., to Miss Gertrude Amy Rosencranz, both of Evansville, Ind., November 11.

William Henry Eason, M.D., Lula, Miss., to Miss Willie Joyner Greer of Potts Camp, Miss., November 5.

Peter Jackson Sherlock, M.D., Lockridge, Ia., to Miss Stella Garbre of Mt. Pleasant, Ia., November 17.

Alfred Townsend Osgood, M.D., to Miss Ethna de Lestere Mackeye, both of New York City, November 24.

Edward Morrison Myers, M.D., Boone, Ia., to Miss Margaret Ross of Frankfort, Ind., November 24.

Jacob Victor Greenebaum, M.D., Cincinnati, to Miss Fannie Frank of Boston, November 22.

Arthur Reeves, M.D., Bladen, Neb., to Miss Flora Wilderman of Pittsburg, Kan., November 9.

John E. O'Neill, M.D., to Miss Catherine Agnes Thuman, both of Baltimore, November 23.

Walter Edward List, M.D., to Miss Beulah Kleespies, both of Cincinnati, November 25.

Deaths

Clinton Wagner, M.D. University of Maryland, Baltimore, 1859; surgeon-in-chief of the Second Division of the Fifth Army Corps of the Army of the Potomac; prime mover in the establishment of several military hospitals, including the first floating hospital on Western waters; founder of the New York Laryngological Society and instrumental in the founding of the American Laryngological Society; first professor of laryngology and rhinology in the New York Post-Graduate Medical School and Hospital; inventor of many surgical instruments and the author of voluminous literature relating to his specialty; died in Geneva, Switzerland, November 25, aged 77 years.

John Walter Grimes, M.D. University of the South, Sewanee, Tenn., 1898; a member of the Medical Association of the State of Alabama; once president of the Talladega County (Ala.) Medical Association; a practitioner of Talladega Springs and surgeon for the Alabama Mineral Division of the Louisville and Nashville System; who moved to Clayton, N. Mex., two years ago on account of tuberculosis; died in that place, November 27, from pulmonary hemorrhage, aged 46.

Euclid Van Zandt, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1878; a pioneer practitioner and for many years county physician of Whatcom County, Wash.; for several years president of the Washington State Medical Association and of the State Board of Medical Examiners; in 1904 appointed superintendent of the State Hospital for the Insane, Fort Steilacoom; died in Bellingham, Wash., November 20, from arteriosclerosis, aged 70.

Darwin Adelbert Stewart, M.D. College of Physicians and Surgeons in the City of New York, 1869; of Winona, Minn.; a member of the Minnesota State Medical Association; in 1902 and 1903 mayor of Winona, Minn.; for ten years coroner of Winona County; for five years city physician, and once president of the school board; local physician for the Chicago, Milwaukee and St. Paul Railway; died in St. Barnabas' Hospital, Minneapolis, November 30, aged 69.

Harry T. Walker, M.D. Keokuk (Ia.) Medical College, 1898; of Dubuque, Ia.; formerly a Fellow of the American Medical Association; a member of the Iowa State Medical Society; a member of the staff of St. Joseph's Mercy Insane Hospital; died in Mercy Hospital, Dubuque, November 30, a few hours after an operation for disease of the kidney, aged 48.

Albert Charles Peale, M.D. University of Pennsylvania, Philadelphia, 1871; for more than thirty years connected with the Smithsonian Institute and the National Museum, Washington; mineralogist and geologist in the government employ in the survey of the territories from 1871 to 1879; and geologist of the U. S. Geological Survey from 1883 to 1898; died in the German Hospital, Philadelphia, December 5, from cerebral hemorrhage, aged 65.

William Terrence Carolin, M.D. Harvard Medical School, 1877; a Fellow of the American Medical Association and formerly a member of the Massachusetts State Board of Health, Lunacy and Charity; died at his home in Lowell, Mass., November 21, aged 62. The active pall-bearers at his funeral were his professional associates in Lowell.

James Sullivan Howe, M.D. Harvard Medical School, 1881; a Fellow of the American Medical Association and American Dermatological Association; professor of dermatology in Tufts College Medical School, Boston; dermatologist to the Boston City Hospital and Boston Dispensary; died at his home in Brookline, Mass., November 22, aged 56.

Benjamin F. Whitmer, M.D. Jefferson Medical College, 1868; formerly a member of the Indiana State Medical Association and for more than thirty-five years a practitioner of Elkhart County; a surgeon in the Federal service during the Civil War; died at his home in Goshen, Ind.; November 22, from cerebral hemorrhage, aged 76.

J. McBride Johnson, M.D. Kentucky School of Medicine, Louisville, 1899; of West Plains, Mo.; a member of the Missouri State Medical Association and a specialist in diseases of the eye, ear, nose and throat; died in a hospital in Springfield, Mo., November 22, from nephritis, aged 42.

Mosheim S. Burgess, M.D. Maryland Medical College, Baltimore, 1907; formerly of Medford, Ore.; died in his office in Wayne, W. Va., November 24, from the effects of a gunshot wound of the head, self-inflicted, it is believed with suicidal intent, aged 34.

Albert Barnes Dorman, M.D. College of Physicians and Surgeons, Boston, Mass., 1892; a member of the Massachusetts Medical Society; a practitioner of Winthrop, Mass., for more than thirty-five years, and for twelve years, chairman of the board of health of that town; died at his home in Winthrop, November 22, aged 59.

William Palmer Melcher, M.D. University of Pennsylvania, Philadelphia, 1876; a Fellow of the American Medical Association; for six years a practitioner of Camden, N. Y.; visiting physician to the Burlington County(N. J.) Hospital; died at his home in Mt. Holly, N. J., November 30, from heart disease, aged 65.

Frederick Enoch Shaw, M.D. Cooper Medical College, San Francisco, 1908; a member of the Medical Society of the State of California; formerly a resident of Haverhill, Mass.; recently elected commissioner of finance of Sacramento, Cal.; died at his home in that city, November 29, from pulmonary hemorrhage, aged 35.

Francis Lester Babcock, M.D. Boston University School of Medicine, 1879; for many years a member of the Dedham (Mass.) Board of Health and for ten years visiting physician to the Norfolk County Home, Dedham; died at his home in East Dedham, Mass., October 27, from cerebral hemorrhage, aged 65.

Samuel Webb Scales, M.D. Vanderbilt University, Nashville, Tenn., 1905; of Starkville, Miss.; surgeon to the John N. Stone Cotton Mills; while crossing the railroad tracks near his home, November 26, in his automobile, was run down by a passenger train and almost instantly killed, aged 34.

William Ernest Walker, M.D. Baltimore College of Dental Surgery, 1889; University Medical College, Richmond, Va., 1900; an Associate Fellow of the American Medical Association and a prominent dentist and oral surgeon of New Orleans; died in the Hotel Dieu in that city, November 21, aged 46.

William Tatum Richmond, M.D. Tulane University, New Orleans, 1882; a Confederate veteran; for many years a practitioner of Manor and Edna, Texas; health officer of Edna and Jackson counties; died at the home of his son in El Paso, Texas, November 22, from heart disease, aged 72.

Warren Morris Babbitt, M.D. New York University, New York City, 1858; assistant surgeon of the Fifty-Fifth Massachusetts Volunteer Infantry and later surgeon of a New York regiment during the Civil War; died at his home in South Braintree, Mass., November 26, from pneumonia, aged 82.

Charles Bailey Simcoe, M.D. Missouri Medical College, St. Louis, 1884; superintendent of the State Institution for Feeble-Minded, Marshall, and later assistant physician at the Nevada State Hospital; died in that institution, November 21, from nephritis, aged 54.

Marshall T. Shively, M.D. Medical College of Ohio, Cincinnati, 1874; a member of the Indiana State Medical Association and a prominent practitioner of Grant County, Ind.; died at his home in Marion, November 23, from cerebral hemorrhage, aged 65.

James Muir Halstead, M.D. Kentucky University, Louisville, 1906; of Ridgway, Colo.; local surgeon for the Denver and Rio Grande System; died in the Mont Rose Hospital, November 14, a few hours after an operation for acute appendicitis, aged 29.

William Wesley Johnson, M.D. University of Pennsylvania, Philadelphia, 1865; of Chester, Pa.; surgeon of U. S. Volunteers during the Civil War; died suddenly while making a professional call in Chester, Pa., October 21, from cerebral hemorrhage, aged 77.

Charles W. Shreve, M.D. University of Maryland, Baltimore, 1858; for many years a practitioner of Dickerson, Md.; died at the home of his son in Washington, D. C., November 24, from the effects of a fracture of the hip three months before, aged 80.

Charles Bertram Powell, M.D. University of Minnesota, Minneapolis, 1894; a Fellow of the American Medical Association and a specialist on diseases of the eye, ear, nose and throat; died at his home in Bemidji, Minn., November 30, aged 43.

Jeptha J. Alford, M.D. Tulane University, New Orleans, 1857; formerly a member of the Louisiana Legislature and a resident of Sunny Hill; one of the oldest residents of Washington Parish; died at the home of his son near Osyka, Miss., November 21.

William Augustine Hewins, M.D. Miami Medical College, Cincinnati, 1878; a Fellow of the American Medical Association; for thirty-five years a practitioner of Chandler, Ind.; died at his home in that place, November 26, from asthma, aged 63.

John Irvine Wiley, M.D. Trinity Medical College, Toronto, Ont., 1889, and gold medalist of his year; a member of the Board of Education of Dresden, Ont.; died at his home in that place, October 15, from pernicious anemia, aged 48.

J. T. Bettis, M.D. Cleveland Homeopathic Medical College, 1869; a veteran of the Civil War; and for more than forty years a practitioner of Livonia, N. Y.; died at his home in that city, November 22, from heart disease, aged 69.

Samuel William Coombs, M.D. Vanderbilt University, Nashville, Tenn., 1885; local surgeon at Bowling Green, Ky., for the Louisville and Nashville System; died at his home November 20, from cerebral hemorrhage, aged 51.

Crawford Johnston, M.D. University of Toronto, Ont., 1907; an early practitioner of Sheridan County, Mont., and a resident of Culbertson; died in the Havre (Mont.) Hospital, November 14, from typhoid fever, aged 32.

Hannibal W. Rand, M.D. University of Vermont, Burlington, 1881; a Fellow of the American Medical Association; health officer of Keene, N. Y.; died in the Mary Fletcher Hospital, Burlington, Vt., November 20, aged 60.

Walter V. Hanscom, M.D. Hahnemann Medical College, Philadelphia, 1890; for sixteen years in charge of a hospital in Rockland, Me.; died at the home of his brother in Haverhill, Mass., November 7, from nephritis, aged 45.

Elton L. Wilson, M.D. Tulane University, New Orleans, 1883; a Fellow of the American Medical Association, and for many years a practitioner of Yell County, Ark.; died at his home in Fowler, Ark., November 26, aged 55.

Thomas Olin Jones, M.D. University of Virginia, Charlottesville, 1875; a member of the Medical Society of Virginia; died at his home in Harrisonburg, Va., November 22, from cerebral hemorrhage, aged 63.

John B. Brierly, M.D. Missouri Medical College, St. Louis, 1888; of Gunn City, Mo.; a member of the Missouri State Medical Association; died in the German Hospital, Kansas City, Mo., November 20, aged 53.

Warren M. Campbell, M.D. Cincinnati College of Medicine and Surgery, 1871; for more than sixty years a practitioner; died at his home in Kansas City, Mo., November 28, aged 87.

Delphius W. Howard, M.D. Hahnemann Medical College, Chicago, 1881; formerly mayor of Independence and Nevada, Mo.; died at his home in Nevada, November 21.

Frederick Seitz, M.D. Jefferson Medical College, 1886; for thirty-eight years a physician and druggist of Philadelphia; died at his home in that city, November 25, from cerebral hemorrhage, aged 63.

William H. Smith, M.D. Western Reserve University, Cleveland, Ohio, 1876; for fifty-eight years a practitioner of Rushville, Ind.; died at his home in that city, November 10, from angina pectoris, aged 80.

John T. Hubel, M.D. Detroit College of Medicine, 1899; examining surgeon to the United States Marine Corps in Detroit; died at his home in that city, November 29, from disease of the lungs, aged 37.

Thaddeus FitzHugh, M.D. Medical College of Virginia, Richmond, 1859; a Confederate veteran; in 1896 appointed postmaster of Kansas City, Kan.; died at his home in that city, November 21, aged 79.

Stephen Clarence Pettit, M.D. Long Island College Hospital, Brooklyn, 1895; died at his home in Brooklyn December 3, from septicemia due to an infected wound received while operating, aged 43.

Louis C. Long, M.D. Northwestern Medical College, St. Joseph, Mo., 1882; for twenty-three years a practitioner of Lincoln, Neb.; died at his home in that city, December 2, from diabetes, aged 57.

Sarah C. Hussey Millen, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1882; of Omaha, Neb.; died in the Nicholas Senn Hospital, Omaha, November 22, from cerebral hemorrhage, aged 59.

Newton Graves, M.D. Western Reserve University, Cleveland, Ohio, 1862; for more than twenty years a practitioner of Stafford; died in the Masonic Home, Utica, N. Y., November 23, aged 86.

J. M. Sheppard, M.D. Baltimore Medical College, 1894; a member of the West Virginia Medical Association; was found frozen to death near his home at Falls Mills, Va., November 21.

Robert McNeilly, M.D. University of Pennsylvania, Philadelphia, 1863; assistant surgeon of Volunteers during the Civil War; died at his home in New York City, November 28, aged 83.

Loren S. Barton Otwell, M.D. Medical College of Ohio, Cincinnati, 1865; a pioneer practitioner of southeastern Kansas; died at his home in Independence, Kan., December 3, aged 87.

Isaac Moore, M.D. St. Louis Medical College, 1870; for many years a practitioner of Alton, Ill.; died in the Deaconess Hospital, St. Louis, November 19, after a surgical operation, aged 67.

William Henry Baldinger, M.D. Jefferson Medical College, 1885; oculist and aurist to the Home for Homeless Children, Galveston, Texas; died recently at his home in Galveston, aged 54.

Ralph H. Augur, M.D. Baltimore Medical College, 1909; a post-graduate worker in John Hopkins Hospital; was found dead in his office in Baltimore, November 27, aged 32.

James Henry Cocke, M.D. Memphis Hospital Medical College, 1900; a member of the Tennessee State Medical Association; died at his home in Moscow, Tenn., November 19.

Michael Richard McGarry, M.D. Dalhousie University, Halifax, N. S., 1908; of Florence, N. S.; died in Harbor View Hospital, North Sydney, N. S., September 23, aged 34.

Welcome Harrison Calfee, M.D. St. Louis Medical College, 1870; Bellevue Hospital Medical College, 1877; of Muskogee, Okla.; died in Big Cabin, Okla., October 21, aged 73.

Stephen H. Gillis, M.D. McGill University, Montreal, 1910; of St. Louis, P. E. I.; died in the Charlottetown, P. E. I. Hospital, September 16, from typhoid fever, aged 29.

Charles R. Crow, M.D. Eclectic College of Physicians and Surgeons, Indianapolis, Ind., 1892; died at his home in Indianapolis, November 27, from neuritis, aged 62.

Frederick W. Kohler, M.D. Jefferson Medical College, 1882; well known as a travel lecturer of Philadelphia; died in the German Hospital in that city, November 27.

J. W. Hogsett, M.D. Medical College of Indiana, Indianapolis, 1875; a veteran of the Civil War; died recently at his home in Lincoln, Kan.

Albert Elliott Wright (license, Michigan, twelve years of practice, 1900) for nearly half a century a resident of Ecorse, Mich.; died at his home, November 28, aged 73.

Willis B. Parks, M.D. Southern Medical College, Atlanta, Ga., 1881; died at his home in Atlanta, November 23, aged 61.

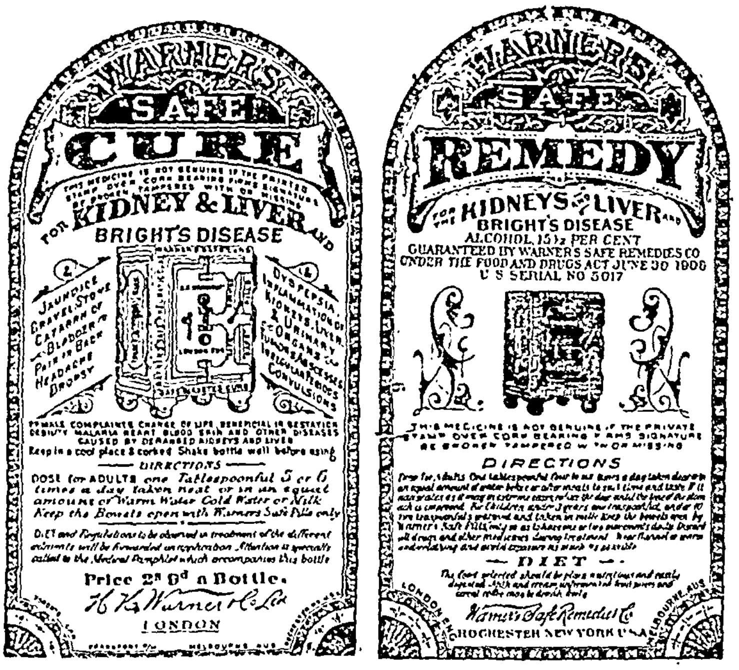
In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

WARNER'S SAFE REMEDY

An Unsafe and Fraudulent Nostrum

"Warner's Safe Remedy for the Kidneys and Liver and Bright's Disease" was sold, not long ago, as "Warner's Safe Cure for Kidney and Liver, Bright's Disease, Urinary Disorders, Female Complaints, General Debility, Malaria and all Diseases caused by Disordered Kidneys and Liver." The company that puts the product on the market was known, until recently, as Warner's Safe Cure Company, Rochester, N. Y. It is now "Warner's Safe Remedies Company." The Warner concern is said to be leased by, and practically a subsidiary company of the New York and Kentucky Company, distillers and wholesale liquor dealers of Rochester, whose business is frankly and openly the manufacture of whiskies. Another subsidiary concern of the New York and Kentucky Company is the Duffy Malt Whiskey Company.

The history of Warner's Safe Remedy is typical of the "patent medicine" business. In the free and easy days, before the public was protected by the Food and Drugs Act, Warner's Safe Cure was advertised extensively — and fraudulently. Efforts were made to impress on the well and the sick the falsehoods that most aches and pains are due to diseased kidneys; that a pain in the back is a sure sign of Bright's disease, and that the only sure cure is the Warner nostrum. The concern went even further in its attempt to frighten people into purchasing Warner's Safe Cure. The advertisements contained what purported to be a sure and simple test for kidney disease. This "test" was led up to by such "scare" claims as:



WARNER'S
SAFE
CURE
This medicine is not genuine if the printed stamp over cork bearing firm's signature be broken tampered with or missing
FOR KIDNEY & LIVER AND
BRIGHT'S DISEASE
Jaundice
Gravel, Stone
Catarrh of Bladder
Pain in Back
Headache
Dropsy
Dyspepsia
Inflammation of Kidneys, Liver, & Urinary Organs
Tumors
Convulsions
Female complaints change of life beneficial in gestation debility malaria heart blood skin and other diseases caused by deranged kidneys and liver
Keep in a cool place & corked Shake bottle well before using
DIRECTIONS
DOSE for ADULTS one Tablespoonful 5 or 6 times a day taken neat or in an equal amount of Warm Water Cold Water or Milk
Keep the Bowels open with Warner's Safe Pills only
Diet and Regulations to be observed in treatment of the different ailments will be forwarded on application. Attention is specially called to the Medical Pamphlet which accompanies this bottle
Price 2s 9d a Bottle.

Reduced facsimiles of the Warner labels as used in the United States (on right) and in the British Isles (on left) after the passage of the Food and Drugs Act. Notice that the "Cure" became a "Remedy" in the United States and the range of diseases for which the stuff is, or was, recommended is much smaller on this side of the Atlantic.

> "At every stroke of the clock a human life goes out. Nearly one-half of all deaths are the result of kidney disease. Nine men and women out of every ten have kidney trouble. If in doubt, try this simple home test":
>
> "Diseased kidneys cause more sickness, suffering and serious complications than any other disease. Thousands of people have kidney trouble and do not know it. If in doubt make this test":
>
> "*Thousands* of men and women have kidney disease and do not know it until it is too late. This simple test will tell":

The "test" by which the susceptible were to be frightened into a belief that they were seriously ill was described thus:

> "Put some morning urine in a glass or bottle; let it stand for twenty-four hours. If then it is milky or cloudy or contains reddish brick-dust sediment, or if particles or germs float about in it, your kidneys are diseased. This is the supreme moment when you should begin to take Warner's Safe Cure *to arrest* all these unnatural conditions, for they are the *unmistakable* symptoms of kidney disease."

They are "unmistakable symptoms" of nothing of the sort. Practically any *normal* urine from a perfectly healthy individual will become more or less cloudy after standing twenty-four hours. "Brick-dust sediment" indicates nothing more serious than concentrated urine and is not an "unmistakable symptom" of "kidney disease." How much mental anguish has been caused by, and how many poor devils have been frightened into purchasing this false and fraudulent nostrum through the villainous suggestion contained in the "test" just quoted there is no means of knowing. That it brought in a golden harvest to the stockholders in Warner's Safe Cure Company, can not be doubted.

With the coming of the Food and Drugs Act, the cruder and more evidently false claims made for this nostrum began slowly to disappear. For some years, however, the lying continued in the newspaper advertising, although certain modifications were made in the labels and cartons. The labels and cartons used in Great Britain, however, continued to bear the same false statements years after the change had been made in the American labels. Such statements as those that follow continued to accompany the trade package of Warner's Safe Cure as sold in Great Britain, long after similar falsehoods had been eliminated from the trade package of the Warner nostrum sold in the United States:

> "Warner's Safe Cure is a purely vegetable preparation . . ."
>
> "It is the only recognized specific."
>
> "Warner's Safe Cure is the most wonderful and beneficent medicine known."
>
> "Backache is the one sure sign of deranged kidneys."

At various times this nostrum has been analyzed and the composition of the product has been described. According to a quotation appearing in the report of the Australian Royal Commission on Secret Drugs, Cures and Foods, the following formula for Warner's "Safe Kidney and Liver Cure" was furnished the German government in accordance with the law:

Extract lycopus virginiana	308	grains
Extract hepatica (herb)	322	grains
Extract gaultheria	7½	grains
Potassium nitrate	39	grains
Alcohol (90 per cent.)	2¼	ounces
Glycerin	10	drams
Water sufficient to make	1	pint

It is reported that as long ago as 1887 the Health Department at *Karlsruhe* issued a warning to the public against the use of Warner's Safe Cure and closed its pronouncement with the statement: "We warn you against buying this useless medicine."

From the formula given above, it will be seen that the essential drugs in the nostrum are alcohol and potassium nitrate. In 1907 the North Dakota Agricultural Experiment Station analyzed the stuff and it, too, found potassium nitrate and alcohol as, also, did the chemists of the British Medical Association in 1909. Still more recently the chemists of the Laboratory of the American Medical Association have examined Warner's Safe Remedy with the following results:

LABORATORY REPORT

One bottle of Warner's Safe Remedy, manufactured by the Warner's Safe Remedies Co., Rochester, N. Y., was submitted to the Chemical Laboratory for examination. The bottle contained a brown murky liquid, having an aromatic flavor, the odor of oil of wintergreen being quite pronounced. The specific gravity of the liquid at 15.6 C. was 1.0653. Qualitative tests demonstrated the presence of potassium, trace of sodium, nitrate, glycerin, alcohol, and extractive matter.

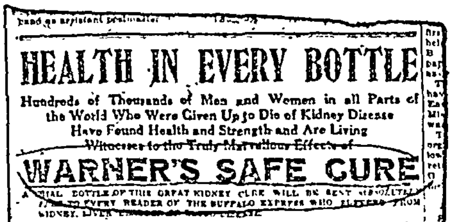
Quantitative estimations yielded the following:

Alcohol (by volume)	14.40 per cent.
Glycerin (by weight)	7.72 per cent.
Pot. nitrate (calculated from 0.68 per cent. potassium)	1.75 per cent.

Each fluid ounce (two tablespoonfuls) contains essentially 4.5 c.c. of 95 per cent. alcohol, 2 c.c. (½ fluid drachm) glycerin and .55 gm. (8½ gr.) potassium nitrate with extractive matter.

Here, then, we have a preparation sold inferentially for the cure of Bright's disease and consisting essentially of alcohol, glycerin and potassium nitrate, with extractives. Alcohol, of course, is contra-indicated in inflammatory diseases of the kidney. Potassium nitrate is a kidney irritant and would tend to aggravate any inflammation that might exist. The label on the bottle of Warner's Safe Remedy declares the presence of 15.5 per cent. alcohol and recommends a dosage of one tablespoonful four to six times a day. The circular wrapped around the bottle recommends "one tablespoonful six or eight times a day." Taken at the maximum dose recommended, one large (pint) bottle of Warner's Safe Remedy would last four days. Such a bottle of Warner's Safe Cure contains an amount of alcohol equivalent to the alcohol in 5 ounces of whiskey. This means that the person suffering from Bright's disease who buys Warner's Safe Remedy and takes it according to directions may get the equivalent of 5 ounces of whiskey every four days. In addition to this he may also be getting a daily dose of 34 grains of potassium nitrate to irritate the kidneys further.

Not only, then, will Warner's Safe Remedy not cure Bright's disease but it may hasten the death of the sufferer who takes it. Those who, suffering from diseases of the kidney, rely on Warner's Safe Remedy, will not only be cruelly defrauded but will, without question, shorten their lives.



HEALTH IN EVERY BOTTLE

Hundreds of Thousands of Men and Women in all Parts of the World Who Were Given Up to Die of Kidney Disease Have Found Health and Strength and Are Living Witnesses to the Truly Marvelous Effects of

WARNER'S SAFE CURE

At every stroke of the clock a human life goes out. Nearly one half of all deaths are the result of kidney disease. Nine men and women out of every ten have kidney trouble. If in doubt TRY THIS SAMPLE HOME TEST.

Cures Kidney Disease

A typical Warner advertisement of a few years ago. Notice the "scare stuff" and the fraudulent "home test."

CYPRIDOL CAPSULES

Report of the Council on Pharmacy and Chemistry

Having voted that Cypridol Capsules be refused recognition, the Council directed that for the information of physicians publication of the following report be authorized.

W. A. Puckner, Secretary.

Cypridol Capsules, sold by E. Fougera & Co., New York, are stated to be "Bottled in the New York Laboratories of Vial, late Rigaud and Chapoteaut, Paris," and to contain, in each capsule, 2 mg. (1/32 grain) mercuric iodid (biniodid of mercury) dissolved in a fatty oil. They are claimed to permit the administration of mercury without danger of salivation—an obvious misrepresentation.[1] Cypridol Capsules are marketed in a way to appeal to the public. If they are once prescribed, the directions on the bottle and the full instructions for the treatment of syphilis by means of Cypridol and by other proprietaries sold by Fougera & Co. is likely to lead the patient to attempt the treatment of his malady on his own accord, and thus probably to forfeit his chances of cure. Cypridol is a vicious example of the "ready-to-take" proprietaries.

Cypridol Capsules are in conflict with the Rules of the Council as follows:

Rule 4: The dosage, price, etc., on the label, and the name "Cypridol" blown in the bottle, all tend to a direct self-prescribing by the public. In addition to the objectionable statements on the bottle itself, the preparation is put up in patent medicine style and is accompanied by a circular giving full directions for the use of this and of other proprietaries for the treatment of syphilis in all of its stages. The circular states that "a 1 per cent. solution of bin-iodide of mercury in an aseptic oil" is "An Improved Specific in the Treatment of Syphilis," and after lauding the virtues of Cypridol, gives full directions for the treatment of syphilis in its various stages by means of Capsules of Cypridol augmented, during periodical cessation of treatment, by "small doses of iodide of strontium (Paraf-Javal's standard solution, thirty grains to the ounce)." Further, the circular expounds the need of "a toning up of the general system" and by means of obsolete theories and obviously untrue assertions recommends "*Chapoteaut's Wine* [another of their proprietary preparations], each ounce of which contains 10 grains of phospho-glycerate of lime. This is a delicious, nutritive tonic. A pint bottle costs $1.00."

Rule 6: Whereas it is evident that Cypridol, depending for its effects on mercuric iodid, the ordinary well-known hydrargyri iodidum rubrum of the U. S. Pharmacopeia, must naturally have the properties of a mercuric compound, unwarranted claims such as the following are made:

> "CYPRIDOL does not render patients anemic. Ptyalism never follows the administration of the capsules or injections. On the contrary, patients rapidly put on flesh and keep well. There are no diarrhoeas or other symptoms of intolerance even when the dose is pushed."

Rule 8: The non-informing name "Cypridol" for a mercuric iodid preparation is bound to lead to its use without consideration of the fact that a potent mercury preparation is being used, requiring a careful adjustment of dosage, a consideration of the needs of the individual case, a correct diagnosis, etc. While the advertising propaganda argues that "physicians recognize the advantage of prescribing this solution of mercuric iodide in an aseptic oil under the name of 'Cypridol,' because it does not betray to the laity the fact that mercury is being used," not only the physician but also the patient has a right to know, and ought to know, the potent character of the remedy which is being administered.

It is recommended that Cypridol be refused recognition and that publication of this report be authorized.

INTESTINAL ANTISEPTIC W-A

Report of the Council on Pharmacy and Chemistry

The Council voted that Intestinal Antiseptic W-A be refused recognition, and that the publication of the following report be authorized.

W. A. Puckner, Secretary.

The Abbott Alkaloidal Company advertises "Intestinal Antiseptic W-A" as

> ". . . A scientifically blended and physiologically adjusted mixture, of the pure sulphocarbolates of calcium, sodium and zinc, grs. 5, with bismuth subsalicylate, gr. 1-4 and aromatics."

---

[1] Physicians who desire to use a solution of mercuric iodid in oil should direct their pharmacist to prepare it according to the method suggested by Lemaire (Repert. pharm., xxi, 97-102, from Chem. Abst., 1909, p. 1444), viz: One gm. of mercuric iodid is dissolved in 50 c.c. sterilized castor oil by warming to about 70 degrees, 3 gm. guaiacol are added and the solution made up to 100 c.c. with sterilized poppy oil. Or according to a later suggestion (Dunning: Proc. Am. Pharm. Assn., 1910, p. 1123): one gm. of mercuric iodid is dissolved in 99 gm. of a mixture of equal parts of sterilized castor and olive oils, by warming on the water-bath.

This formula is in conflict with Rule 1 in that it does not state in what proportion the sulphocarbolates are present.

The name "Intestinal Antiseptic W-A" is in conflict with Rules 4 and 8, since it is therapeutically suggestive.

The preparation is in conflict with Rules 6 and 10, in that exaggerated claims are made for it, no evidence being submitted to prove the superior value of the mixture.

The most serious of these conflicts consists in the exaggerated and misleading therapeutic claims. The advertisements say:

> "This combination has no equal as an antiseptic and inhibitive agent in typhoid fever, diarrhea, dysentery," etc.
>
> "Numerous cleverly devised and scientifically constructed *intestinal* antiseptics have been introduced to the profession, but not one of *them* has ever rivaled for one moment these salts in popularity."
>
> ". . . we are convinced that no small share of the credit for the reduction of the death rate in infantile diarrheas is due to the widespread application of this general method of treatment, associated of course with the calomel clean-out and the *regulation of diet, now* known to be essential."
>
> "But the use of the sulphocarbolates is not restricted to diseases of the alimentary canal, although in the summer diarrheas, gastric fermentation, intestinal indigestion, typhoid fever, dysentery—indeed in all alimentary disturbances—it is the one essential remedy. It is also indicated in practically all infectious diseases."
>
> "Typhoid Fever (in this disease the W-A Intestinal Antiseptic is of great value; used early, with the proper synergistic cleanout, it will often cut short the disease)."

These extreme claims exceed the limits of permissible optimism, unless they are supported by strong dependable evidence. They contrast sharply with the low esteem in which the phenolsulphonates (sulphocarbolates) are generally held. To accept these claims, and to justify encouraging physicians to rely on them, it would be necessary to establish:

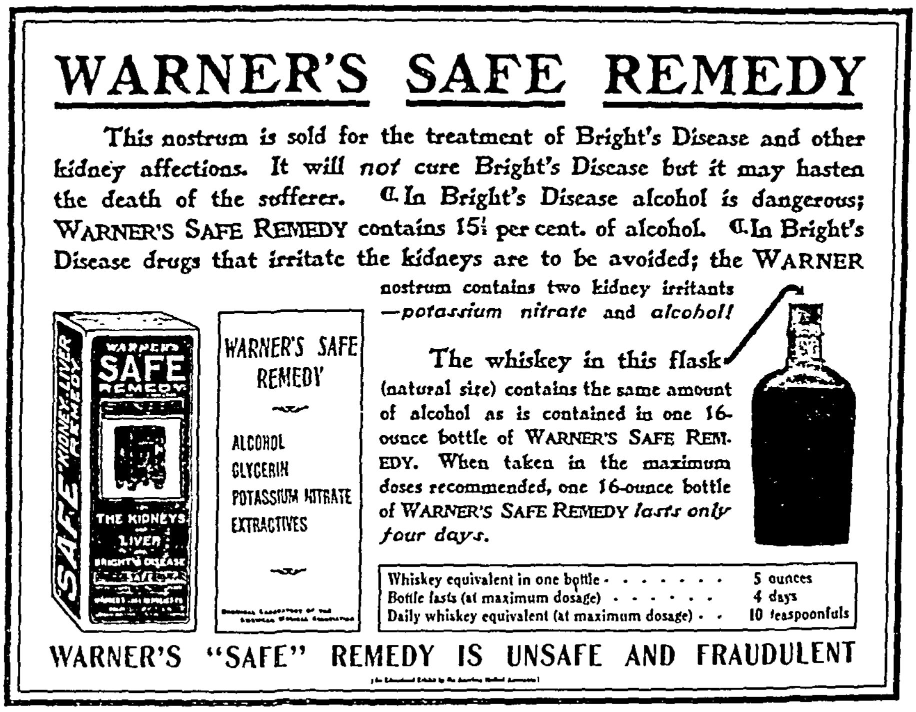
First, that feasible concentrations have a distinct antiseptic action on cultures of intestinal bacteria. This experiment could be easily made, but the claims do not seem to be based on evidence of this kind.

Second, that the preparation actually checks putrefaction in the intestines. There are several methods by which this proof may be attempted; but the claims do not appear to be based on evidence of this kind.

Third, that the preparation actually has a favorable influence on the progress of diseases. This sort of evidence is exposed to so many fallacies that it would have to be gathered very carefully and critically, duly discounting the effect of other treatment; for instance, by comparison with similar cases which do not receive this preparation. This is especially important; and yet we find directions to use this preparation in conjunction with active cathartic treatment, which in itself has considerable influence on the conditions for which this preparation is recommended. No evidence of this kind is presented.

The testimonials contained in the advertisements cannot be considered as serious evidence. None present any indication of accurate record, or proper control of conditions; of the performance of control observations. They are superficial impressions, to which little or no weight can be attached.

It is recommended that Intestinal Antiseptic W-A be considered ineligible for New and Nonofficial Remedies.



WARNER'S SAFE REMEDY

This nostrum is sold for the treatment of Bright's Disease and other kidney affections. It will *not* cure Bright's Disease but it may hasten the death of the sufferer. ¶ In Bright's Disease alcohol is dangerous; Warner's Safe Remedy contains 15½ per cent. of alcohol. ¶ In Bright's Disease drugs that irritate the kidneys are to be avoided; the Warner nostrum contains two kidney irritants —*potassium nitrate* and *alcohol!*

The whiskey in this flask (natural size) contains the same amount of alcohol as is contained in one 16-ounce bottle of Warner's Safe Remedy. When taken in the maximum doses recommended, one 16-ounce bottle of Warner's Safe Remedy *lasts only four days.*

Whiskey equivalent in one bottle	5 ounces
Bottle lasts (at maximum dosage)	4 days
Daily whiskey equivalent (at maximum dosage) . .	10 teaspoonfuls

WARNER'S "SAFE" REMEDY IS UNSAFE AND FRAUDULENT

Miniature reproduction of an educational poster prepared by the Propaganda for Reform Department. Twenty-eight different posters already prepared, illustrate various phases of the evils of nostrums and quackery. In the original the placards measure 22 by 28 inches. A catalog of the complete set will be sent on request.

Correspondence

Justice and Science

To the Editor:—In the evolution of medical education, which is going on so rapidly at the present time, a condition has arisen which is anomalous and certainly, from more than one point of view, fundamentally wrong. The proposition is being brought forward, and in some instances is being carried out, to have full-time teachers of medicine and surgery and their allied branches, on salaries of ten thousand dollars or more per year. With the question of the wisdom of full-time professorships in the practical departments of medicine, a matter which is still under debate, I do not wish to deal, but I do want, as a clinician, to speak a word about the injustice which this plan works to the men who are equally deserving of large salaries, not only because of their ability, but because they have deliberately devoted themselves to their special departments of medical science as teachers and investigators, and, in order to be *facile princeps* in their respective departments, have deliberately narrowed their opportunities of making a living. I refer to professors of the so-called fundamental branches in medicine, viz.: chemistry, anatomy, physiology, bacteriology and pathology, who are receiving as a maximum salary four to five thousand dollars per year. It would seem, now that it is so universally agreed that these men shall give their whole time to teaching and investigation, that the next effort should be to see that funds are raised for their generous support and that the collecting of money with which to pay salaries to full-time professors in clinical departments should wait until those men who are already giving their full time are adequately provided for.

It may be said that a clinician cannot be obtained for a full-time professorship for less than ten thousand dollars a year and that a teacher of one of the fundamental branches of medicine can be gotten for five thousand dollars, and that, therefore, the proposition is purely a commercial one, based upon the law of supply and demand; but is this the best way to advance medical science or medical teaching, and is it just? Shall it be said to a young man who is starting on his career, "If you go into medical science and do good work, for a number of years you will receive a mere pittance as an assistant and, when you reach the ultimate goal, a professorship, you will never get more than five thousand dollars yearly, whereas, if you go into clinical medicine or surgery you will before long be self-supporting from your practice, and when you become a professor you will get ten thousand dollars annually"?

For the advance of science three things are necessary. First, devotion to its cause. Second, a mind free from the unavoidable annoyances of a meager salary, and, last, a consciousness that the world in general, and medical men in particular, are enthusiastic and generous supporters of all of those who unselfishly use their great abilities for the good of science rather than for their personal gain. Do the men who control large sums of money, and do the men who control scientific institutions really intend to make such invidious distinctions between able men in clinical medicine and surgery on the one hand and equally able men in the fundamental medical sciences on the other, as to say to a clinician, "We will pay you ten thousand dollars," and to another man, "As you are a physiological chemist or pathologist, we will pay you only five thousand dollars"?

Both men are at liberty at any time to resign their professorships. The clinician on resigning is practically guaranteed a greater income by reason of the title which he has borne in a great institution. The other man, having devoted himself solely to a non-clinical scientific pursuit, has no means of gaining a livelihood except by finding another professorship at a salary no larger than that which he has given up.

In other words, while we discuss the abstract problem of full-time clinical professors, had we not better devote our energies in properly providing for the full-time men already engaged? These are they who not only set an example to the student of unselfish devotion and who perform their task for the work's sake, but who also in most instances lay the foundation upon which the clinician can build. Taking it all in all, is it not a fact that the average investigator and teacher, possessing the genius of original research, is deserving of reward at the hands of colleges and universities at least to the same extent as any other appointee?

H. A. Hare, M.D., Philadelphia.

Importance of Geriatrics

To the Editor:—Canstatt (Krankheiten des höheren Alters und ihre Heilung, Erlangen, 1839) says:

> "Medical literature, especially of the present day, abounds in works on diseases of women and children. The pathology of certain organs and of certain classes of diseases receives exceptional attention. Bare and neglected in comparison with these lovingly fostered medical studies is a field which, if it were cultivated, promises fruitful returns." (Free translation.)

Charcot, in his "Clinical Lectures on the Diseases of the Aged" (Hunt's American translation, 1881), says:

> "The importance of a special study of the diseases of old age cannot be contested at this day. We have come to recognize in reality that, if the pathology of childhood countenances clinical considerations of a special kind, and if it is indispensable that it be known from a practical point of view, then also senile pathology presents its difficulties, which cannot be surmounted except by long experience and a profound acquaintance with its peculiar characteristics."
>
> "The progress of age establishes a wide difference in pathological phenomena, by virtue of its physiological modifications. . . . There do exist special diseases of old age which, in part at least, arise from the general modifications which the economy has undergone. . . . I think enough has been advanced to convince you that a *senile* pathology does exist."

Seidel in his monograph on "Diseases of Old Age" (Wood's monographs, 1890) says:

> "Mistakes are made daily in the treatment of the aged, and the normal mortality of advanced life is considerably increased as a consequence of the hitherto neglected study of the anatomical and physiological peculiarities of the senile organism."

Schwalbe in his "Lehrbuch der Greisenkrankheiten," Stuttgart, 1909, referring to the selection from Canstatt quoted above, says:

> "These still apply in full force, and the fact is more noticeable to-day than it was in the fourth decade of the last century."

The subject is taken up seriously in Germany and especially in France, where three text-books have appeared within a few years. Saundby (Old Age, Its Care and Treatment, London, 1913) quotes fifty-one dated works. Of these, twenty-one are English but only four are of the present century. Of nineteen French works, sixteen are of the present century, and of eleven German works eight appeared since 1900. Not a single American author is quoted, and of 446 authors quoted by Schwalbe there are only six Americans, and three of these are really German physicians. In 1911 five theses on senile conditions were presented to the French Academy. I will not take up here the many reasons why geriatrics should take a place in medicine analogous to pediatrics. I will point out, however, that the pediatrist does not look on the child as an adult with incompletely developed organs and tissues but as a *child*; and the geriatrist (I think the term is applicable) does not look on the aged person as an adult having pathologically degenerated organs and tissues, but as an aged person. The lack of an adequate term expressing the aged person, like the German *Greis*, or the French *vieillard*, has perhaps some influence in perpetuating our antiquated point of view of the aged. If we will realize, for example, that in the aged the normal systolic pressure is about the age plus 100 in millimeters, that the erythrocyte count is about 3,600,000, and that the polynuclear leukocytes are increased, that the urine is diminished in amount, that the urea output is greatly lessened, that albumin and sugar are frequently found without other evidence of nephritis or diabetes, that the normal expiration is about 20 a minute, yet the carbon dioxid output is from 20 to 40 per cent. less than in maturity, etc., we shall not make efforts, such as are often made now, to restore such conditions to the norm of maturity. With a knowledge of senile anatomy and physiology and senile pathology, we can clear ourselves of Seidel's justified charge, for it holds as good to-day as it did nearly twenty-five years ago. The subject, if not the name, is recognized in Germany and it is studied in France, while we are so intent in our efforts to lead the world in surgery and child welfare that we neglect the less promising, less interesting, less remunerative, economically deficient, aged.

Part of what I have said applies also to the public care of the aged. To those who are sufficiently interested in the well-being of the aged to study their welfare, I would recommend a visit to the New York City Farm Colony and compare the result of suitable employment for the aged with other institutions where the aged inmates are not employed. Compare the mental and physical condition of the inmates in homes where the sexes are segregated with these conditions where they are not segregated. The study of the needs, the peculiarities and infirmities of the aged will show how irrational are our present antiquated methods of dealing with the aged.

I. L. Nascher, M.D., New York.

Facts Concerning Reported Discovery of Germ of Gas Gangrene

To the Editor:—Information has come to us that reports have been circulated by a number of American newspapers announcing the discovery by us of the germ of gas gangrene and of a serum for the prophylactic and curative treatment of this condition. We were at first tempted to let these reports pass unnoticed, but, on reflection, we feel that they should not go uncorrected.

The only possible foundation for such an announcement is the fact that we did make bacteriologic studies in a series of cases of so-called "gas" gangrene, and that in a number of them, we were able to isolate *Bacillus perfringens*. Our findings have since been confirmed by Dr. Weinburg of the Institut Pasteur, who has been requested by the French government to make a thorough bacteriologic investigation of the condition. As for our reported discovery of a serum for the treatment of "gas" gangrene, that is a "discovery" of the bacteriologic laboratories of the Associated Press, in which so many other wonderful discoveries have originated.

LITERATURE ON ROENTGENOSCOPY OF THE GASTRO-INTESTINAL TRACT

To the Editor:—Please give me information concerning roentgenoscopic diagnosis of diseases of the intestinal tract.

Douglas Ford Robbins, M.D., Minneapolis.

Answer.—The following is a list of literature on this subject:

Mills, R. Walter: Points of Value in Roentgenoscopy of Gastro-Intestinal Tract, The Journal, Oct. 11, 1913, p. 1344.
Chapin, H. D.: Radiographic Studies of Gastro-Intestinal Tract in Infants, The Journal, Oct. 8, 1913, p. 1419.
Case, J. T.: Roentgenologic Observations on Function of Ileocolic Valve, The Journal, Oct. 3, 1914, p. 1194.
Clark, L. P., and Busby, A. H.: Value of Roentgen Analysis of Gastro-Intestinal Tract in Some Types of So-Called Functional Nervous Disorder, The Journal, Feb. 7, 1914, p. 440.
Cannon, W. B.: Early Use of Roentgen Ray in Study of Alimentary Canal, The Journal, Jan. 3, 1914, p. 1.
Carman, R. D.: Technic of Roentgen Ray Examination of Gastro-Intestinal Tract in Interpretation of Screen and Plate Findings, The Journal, Aug. 2, 1913, p. 321.
Albu, A.: Roentgenoscopy in Gastro-Intestinal Disease, *Med. Klin.*, March 1, 1914.
Brown, P.: Roentgenologic Consideration of Relation of Individual Type to Intestinal Stasis, *Boston Med. and Surg. Jour.*, Oct. 15, 1914.

KELLER'S TUBERCULIN TEST PLATE

To the Editor:—1. What is Keller's Tuberculin Test Plate?
2. Is it reliable for the early diagnosis of tuberculosis? X. Y. Z.

Answer.—1. Keller's Tuberculin Test Plate is a piece of adhesive plaster about the size of a common bunion plaster, in the middle of which is a circle about 2 cm. (0.8 inch) in diameter containing an ointment-like material. The nature of the salve must be judged by its effects. The following are the directions for applying the Tuberculin Test Plate:

> Any convenient place on the abdomen, chest or back may be selected. A little alcohol may be applied if the skin is oily; otherwise it is sufficient to rub gently with dry gauze until very slightly reddened. The parts should be dry when the Plate is applied.
>
> Remove the protective covering, applying the Plate by means of the adhesive, using such force as necessary to cause it to firmly adhere. It should be allowed to remain undisturbed twenty-four hours, at the end of which time it is removed. It is never necessary to apply longer than twenty-four hours.
>
> A positive reaction is evidenced by the appearance of a number of fine red papules. These may be present at the time the Plate is removed, or they may not appear until twenty-four or forty-eight hours later. Also there may be a few present, and more appear later. No opinion therefore should be given until the end of that period.
>
> It is convenient and practicable to designate the reaction by the number of papules: Less than ten, a slight reaction; up to thirty, medium, and larger numbers, a marked reaction.

From the effects described, it seems safe to assume that the material contains tuberculin, and, judging from the mode of application, it is the Moro ointment. This preparation consists of equal parts of old tuberculin and anhydrous lanolin.

2. The Moro test is reliable in case of a positive reaction to determine the presence of tuberculosis in the organism, but it does not discriminate between active and latent tuberculosis. As nearly every person has experienced tuberculous infection before reaching adult life, a large majority of adults give a positive reaction to it. Used by the experienced physician, it may yield valuable information in case of children suspected of tuberculosis. However, as a secret test much needless anxiety will be caused by it.

ATTENDANCE BY PHYSICIAN ON WIFE IN CONFINEMENT

To the Editor:—Is it legal and ethical for a physician to attend his own wife in confinement in the state of Michigan? S. C. J.

Answer.—Yes.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Alabama: Montgomery, Jan. 5, 1915. Chairman, Dr. W. H. Sanders, Montgomery.
Alaska: Juneau, Jan. 5, 1915. Sec., Dr. H. C. DeVighne, Juneau.
Arizona: Phoenix, Jan. 5-6, 1915. Sec., Dr. John Wix Thomas, 200 Nat'l Bank of Ariz. Bldg., Phoenix.
Illinois: Chicago, Jan. 13-15, 1915. Sec., Dr. C. St. Clair Drake, Springfield.
Indiana: Indianapolis, Jan. 12-14, 1915. Sec., Dr. W. T. Gott, State House, Indianapolis.
Iowa: Des Moines, Jan. 19-21, 1915. Sec., Dr. Guilford T. Sumner, Capitol Bldg., Des Moines.

South Dakota: Pierre, Jan. 12, 1915. Sec. Dr. P. B. Jenkins, Waubay.
Utah: Salt Lake City, Jan. 4-5, 1915. Sec., Dr. G. F. Harding, 407 Templeton Bldg., Salt Lake City.
Vermont: Montpelier, Jan. 11-13, 1915. Sec., Dr. W. Scott Nay, Underhill.
Washington: Walla Walla, Jan. 5, 1915. Sec., Dr. C. N. Suttner, Baker Bldg., Walla Walla.
Wisconsin: Madison, Jan. 12-14, 1915. Sec., Dr. John M. Beffel, 3200 Clybourn St., Milwaukee.

Kentucky June Report

Dr. A. T. McCormack, secretary of the State Board of Health of Kentucky, reports the written examination held at Louisville, June 15-17, 1914. The total number of subjects examined in was 11; total number of questions asked, 110; percentage required to pass, 70. The total number of candidates examined was 56, of whom 50 passed and 6 failed. The following colleges were represented:

PASSED College	Year Grad.	Per Cent.
Chicago College of Medicine and Surgery	(1914)	94
Kentucky School of Medicine	(1908)	73
University of Louisville (1910) 82; (1912) 88; (1914) 81, 81, 82, 82, 82, 82, 82, 82, 83, 83, 84, 84, 84. 84, 85, 85, 85, 86, 86, 86, 86, 87, 87, 87, 87, 87, 87, 87, 87, 87, 88, 88, 88, 88, 90, 90, 92.		
Eclectic Medical College, Cincinnati	(1914)	82
Jefferson Medical College	(1913)	90
Lincoln Memorial University	(1913) 80; (1914)	82
Meharry Medical College	(1911) 73; (1914)	82
University of Tennessee	(1914)	87
Vanderbilt University	(1913) 94; (1914)	84
FAILED		
Bennett Medical College	(1913)	69
Louisville Medical College	(1906)	60
Louisville National Medical College	(1912)	71*
University of Louisville	(1910) 50; (1911)	74*
American Eclectic Medical College	(1893)	42

* Fell below the required average in one or more subjects.

The following questions were asked:

ANATOMY

1. Name the bones entering into the formation of the pelvis and give the articulations. 2. Describe the tibia, giving its articulations and points of muscular and ligamentous attachments. 3. Describe the diaphragm and name the openings connected with it. 4. Describe the right and left subclavian arteries, giving points of difference between them. 5. Give the origin of the superior mesenteric artery and its distribution. 6. Give the origin and distribution of the sciatic nerve. 7. Name the membranes of the spinal cord, giving their relations. 8. Name and describe the fissures of the brain. 9. Locate and describe the ligamentum teres. 10. Describe the inguinal canal.

PHYSIOLOGY

1. Name the different layers composing the walls of the stomach and give the function of each. 2. Name and discuss several causes of indigestion. 3. Classify foods and tell how to prepare a substitute for mother's milk on a physiologic basis. 4. Give the origin of the various constituents of the blood and describe its circulation. 5. Describe the kidney and functions of its different parts. 6. Describe the construction of the teeth and tell how to preserve them. 7. What are the functions of (a) cornea, (b) iris, (c) retina? 8. (a) What are the

functions of muscles? (*b*) Differentiate microscopically between voluntary and involuntary muscles. 9. Discuss the ventilation of a one-room schoolhouse. 10. How is fat digested?

CHEMISTRY

1. (*a*) What is a carbohydrate? (*b*) A hydrocarbon? (*c*) Give example of each. 2. (*a*) Does the pancreatic juice give an acid or an alkaline reaction? (*b*) To what chemical, or chemicals, is the reaction due? 3. Name two preparations of sodium, giving chemical name and pharmaceutical or common name and symbols. 4. (*a*) Define and give example of a chemical symbol; (*b*) a chemical formula. 5. (*a*) Give an antidote for acute arsenical poisoning. (*b*) How would you prepare it? 6. (*a*) What is a source of ptyalin? (*b*) What effect does it have on starches? (*c*) Do acids decrease or increase its activity? 7. (*a*) What symptoms would lead you to believe you had a case of chronic lead poisoning? (*b*) What is the antidote? 8. (*a*) Give the symbols of silver. (*b*) Potassium. (*c*) Mercury. (*d*) Gold. (*e*) Formula of water. 9. (*a*) What do you understand by the term "oxidation"? (*b*) Give an example. 10. (*a*) Is water an element or a compound? (*b*) What is water, chemically considered?

BACTERIOLOGY

1. Define (*a*) culture, (*b*) asepsis, (*c*) antisepsis, (*d*) disinfection, and (*e*) germicide. 2. (*a*) Give morphology of tubercle bacillus. (*b*) What are the channels of infection? 3. What are aerobic and anaerobic bacteria? 4. What is sterilization? 5. (*a*) What is immunity? (*b*) How is it acquired? 6. (*a*) Describe the Klebs-Loeffler bacillus. (*b*) Discuss diphtheritic antitoxin. 7. (*a*) Of what significance is the Widal reaction in typhoid fever? (*b*) Describe it. 8. Give conditions favoring bacterial growth and antagonistic to it. 9. (*a*) Mention some culture mediums. (*b*) How is a pure culture made? 10. Differentiate between contagion and infection, and the means employed to prevent either.

ETIOLOGY AND PHYSICAL DIAGNOSIS

1. (*a*) Define heart block. (*b*) At what age does it most frequently occur? 2. (*a*) Give etiology of malarial fever; (*b*) of yellow fever, and (*c*) mode of transmission to man. 3. (*a*) Give etiology of endocarditis, and (*b*) the two diseases most frequently leading to it. 4. Mention five frequent causes of asthma. 5. Give etiology of arteriosclerosis. 6. Define physical diagnosis and give names of five methods used in examining the thoracic organs. 7. Enumerate the symptoms of catarrhal jaundice; name two other diseases of this region that may resemble it, and differentiate them from catarrhal jaundice. 8. Enumerate the symptoms and physical signs of diffuse peritonitis, and name six conditions within the abdomen that may simulate it. 9. Describe the natural heart sounds, and the causes of each. 10. Name the causes of ascites, and tell how it may be discovered.

HYGIENE, MEDICAL JURISPRUDENCE, MENTAL AND NERVOUS DISEASES

1. In what way and how is carbon dioxid deleterious to health? 2. How would you construct a camp for those suffering from a contagious disease? 3. Name four diseases that are communicable to man through cow's milk. 4. How would you thoroughly inspect meat for the market? 5. What rules would you advise to prevent the spread of tuberculosis? 6. (*a*) Diagnose and treat infantile paralysis; (*b*) locomotor ataxia. 7. Describe and treat herpes zoster. 8. How would you take a dying statement? 9. How would you construct a post-mortem examination in a case of suspected arsenic poisoning? 10. Diagnose and treat a case of psoriasis.

OBSTETRICS AND GYNECOLOGY

1. Define (*a*) ovulation, (*b*) menstruation, (*c*) abortion, (*d*) version, and (*e*) subinvolution. 2. What is (*a*) ovaritis? (*b*) salpingitis? (*c*) What is the most frequent cause of each? 3. (*a*) What is dysmenorrhea? (*b*) Give causes and symptoms. 4. (*a*) What is puerperal septicemia? (*b*) What precaution would you take to *prevent it?* 5. (*a*) Give function of placenta. (*b*) What difficulties may you expect to encounter in its delivery? 6. (*a*) Tell exactly how you would manage a breech presentation. (*b*) What precautions would you take? 7. (*a*) Give indications for the use of forceps. (*b*) State how you would apply them. 8. (*a*) What is the most frequent cause of post-partum hemorrhage? (*b*) How would you manage a case? 9. Give methods of diagnosing pregnancy at the end of the tenth week. 10. (*a*) What is eclampsia? (*b*) Under what condition may you expect it?

OPHTHALMOLOGY, OTOLOGY AND LARYNGOLOGY

1. Under what circumstances would you advise the enucleation of the eyeball? 2. Differentiate between trachoma and blepharitis marginalis. 3. Give etiology and symptoms of glaucoma. 4. Give symptoms and etiology of iritis. 5. Under what circumstances would you puncture the membrana tympani? 6. Give etiology, symptoms and probable sequelae of acute otitis media. 7. (*a*) What are the symptoms of impacted cerumen? (*b*) How would you manage a case? 8. (*a*) Give etiology of mastoid abscess. (*b*) How would you diagnose same? 9. (*a*) What are the indications for intubation? (*b*) Give technic of the operation. 10. Give symptoms and management of a case of postnasal polypi.

PATHOLOGY

1. Name the varieties of leukocytes, and give the percentage of each found in normal blood. 2. Name and describe the pathology of the various stages of lobar pneumonia. 3. Give the pathologic changes found in acute infantile paralysis (*anterior poliomyelitis*). 4. Differentiate between gross symptoms of benign and malignant tumors of the breast. 5. Differentiate between the microscopic examination of (*a*) fibromas, (*b*) sarcomas, and (*c*) carcinomas of the breast. 6. Give the pathology of ulcer of the stomach. 7. *Differentiate* between ulcer and carcinoma of the stomach. 8. Describe the stomach and liver found post mortem in a chronic alcoholic. 9 and 10. Select four of the five slides and make a diagnosis.

PRACTICE OF MEDICINE AND MATERIA MEDICA

1. How would you diagnose a case of diphtheria, describe the trea ment in detail and tell when it would cease to be infectious. 2. Ho would you confirm a diagnosis of malaria, and how would you treat i 3. Describe in detail the treatment of syphilis. 4. What sympton would lead you to suspect hookworm disease, and how would you co firm the diagnosis? 5. Give the treatment in detail for a 12-year-o child weighing 72 pounds having hookworm disease. 6. Give physiolog action, therapeutics and dosage of tincture of aconite. 7. Give in det *the prevention and curative treatment of tetanus and discuss the phy ology of each step.* 8. *How would you treat an acute suppurative pe tonitis?* 9. Tell how to *immunize a patient against typhoid fever.* 1 How would you treat chronic constipation and how would you pr vent it?

SURGERY

1. How would you treat a fracture of the femur? 2. Give diagnost symptoms of fracture of the base of the skull. 3. How would y recognize an abscess of the appendix and what treatment would y advise? 4. How would you recognize intestinal obstruction and wh treatment would you advise? 5. If the foot were crushed at the ank where would you advise amputation, and why? 6. What treatme would you advise in a depressed fracture of the vault of the skul 7. How would you treat a Colles' fracture of the forearm? 8. Wh would be the indications for operation in a penetrating wound of t abdominal wall? 9. How would you treat a comminuted fracture of t olecranon process of the ulna? 10. What treatment would you advi in cancer of the breast?

Michigan June Report

Dr. B. D. Harison, secretary of the Michigan State Boar of Registration in Medicine, reports the written examinati held at Ann Arbor, June 9-11, 1914. The total number subjects examined in was 14; total number of questio asked, 100; percentage required to pass, 75. The total nur ber of candidates examined was 57, of whom 56 passed ar 1 was conditioned. The following colleges were repr sented:

PASSED

College	Year Grad.	Pe Ce
Chicago College of Med. and Surg.	(1912)	87.
University of Illinois	(1914)	86.
University of Louisville	(1914)	76.
University of Michigan, Dept. of Med. and Surg.	(1910) 85.1; (191 89.6; (1913) 78.4, 85; (1914) 83.1, 83.5, 84.7, 84.9, 85.6, 86, 86.3, 86. 86.3, 86.4, 86.5, 86.8, 87.3, 87.4, 87.5, 87.5, 87.7, 87.7, 87.8, 87.8, 87. 87.9, 87.9, 88, 88, 88, 88.2, 88.3, 88.3, 89, 89.1, 89.4, 89.6, 91.9.

that you belong to a profession; never be too intimate with any one around the house. 5. Don't ever tell the household what the doctor says—don't gossip. 6. Don't forget that the doctor should give prognosis and diagnosis. 7. Don't fail to anticipate anything possible that could contribute to the comfort of your patient. 8. Don't forget that noises must be avoided. Your shoes must not squeak. Noisy shoes may seem a small matter to you, but at times will greatly disturb your patient. Move furniture softly. 9. Don't forget that neatness about the patient's room, as well as yourself, is absolutely essential. 10. Don't forget that your teeth must be beyond criticism, as the breath is foul if they are dirty or decayed. 11. Don't forget you must serve your food in an appetizing way, be it a glass of buttermilk or a tray full of dishes. 12. Don't ask sick patients what they want to eat. 13. Don't forget that promptness is everything. The patient must not remind you of the time for medicine, food, bath, etc. 14. Don't ever offer an excuse of any description for anything either to doctor or patient. 15. Don't whisper about the sick room. 16. Don't forget that cleanliness is next to godliness. 17. Don't slam doors. 18. Don't ever forget that you stand between the dead and the living—and your mission is to relieve God's sufferers, and *do be amiable.*—J. D. GRIFFITH, M.D., Kansas City, Mo.

Protection Against Cold for Troops in the Field

A German translation has recently appeared of a Japanese work describing the measures to protect against cold which were found most effectual in the Japanese army during the winter campaign in Manchuria. Every man had an extra pair of boots, mittens and foot cloths, to change at night. They were made to eat often and to keep awake those inclined to drop to sleep on the march or in changing guards. They were kept from doing exercise that would make them sweat, and they were not allowed to lie down on snow. When straw was not available, they had to shovel the snow away so as to lie on the ground. The clothes and shoes were made larger for winter than for summer wear, to allow for layers of air. The buttonholes and other openings were protected with special care, after small frozen areas had been found on the chest of some of the soldiers, corresponding to the buttonholes. The fingers and feet were rubbed with tallow or other unsalted fat, and mittens were worn over gloves. The mittens were sometimes packed with straw or feathers and the shoes with horse bedding. Fur keeps out the wind better than woolen, and a fur abdominal band proved a great help in extremely cold weather. Flannel suspensories were found indispensable to protect at the latrines. Muffs of fur or felt and wristlets of wool or fur are highly recommended. Whenever the hands were found frozen, it was learned that the men had been wearing knitted gloves. The foot cloth worn instead of socks can be dried in emergencies by wearing it next the body. Wrapping the toes in paper, or the whole foot in a pig bladder was also found useful at times. Battalions were provided with flint and steel for starting a fire when matches were lacking or too damp to light.

The "Work Treatment" of Organic Diseases

One of the distressing phases of many crippling diseases is the patient's hopeless despair at being unable to hold his place in the world. Herbert J. Hall (*Boston Med. and Surg. Jour.*, Aug. 6, 1914), remarks that, while it has come to be recognized that suitable mental and physical occupation is an indispensable feature of the treatment of the functional nervous diseases, the relief which properly adapted work may afford in organic diseases—chronic, partly disabling conditions—is not yet sufficiently understood. The good results are the saving of the patient's self-respect and interest in life, the economic benefit from his earnings if he is poor, and in some conditions actual physical improvement. In many chronic arthritis cases, Hall says, the muscular spasm and joint thickening yield more readily to purposeful industrial movements than to massage or other remedial exercises. The interest in accomplishing something relieves the muscular tension. In ataxic cases patients grow intensely weary of the meaningless Frenkel exercises. Hall cites the case of a woman apparently doomed to progressive disease of the spinal cord whose gait was greatly improved and whose whole outlook on life was immeasurably brightened through taking up hand weaving, which involves the use of from two to six foot pedals besides the dexterous throwing of a shuttle. In many cases of progressive blindness, it is suggested, a gain would be made if, during the coming on of the blindness, the patient were taught a trade which could be carried on with pleasure and profit after blindness was complete.

A number of institutions have adapted various crafts to therapeutic uses. Hall mentions the state colony for the insane at Gardner, Massachusetts, where practically all of the 1,200 patients are kept at work. Under skilled directions the patients make all their clothing, even producing on the place the material for woolen garments. In addition they raise all their own food-supplies, reclaim land and erect new buildings. The Massachusetts General Hospital has established under its own roof workshops for certain chronic outpatients who would otherwise be unable to find employment. The Burke Foundation in New York City finances a series of workshops for patients with incurable chronic heart disease, who would break down under ordinary industrial conditions, but who are thus enabled to become partially self-supporting, and thereby to retain much satisfaction in life.

Hall warns against several mistakes likely to result in discouragement, such as the employment of meaningless work which results in nothing useful or beautiful and permitting overwork or any work at all in unsuitable conditions or at unsuitable times. At the same time, he believes that the risk of overdoing has been largely exaggerated, and that the injunction to "make the patient comfortable; do not bother him with work" too often means a lifetime of unhappiness.

It is best to allow the patient to do work which follows the lines of his old occupation if this is possible. Still, patients whose ordinary vocation is rendered unsafe, sometimes take up new trades with surprising facility. Thus a blacksmith or teamster with a badly compensated heart may become a good hand weaver or maker of clothing. Almost any trade may be adapted. "The important thing to remember is that work should be supplied in some form, even in organic illness, whenever the conditions can be made possible."

Acute Toxic Reaction to Atophan

G. Marañon, editor of the *Revista Clinica de Madrid,* reports from his own practice, in the issue of July 30, 1914, two cases of acute intoxication from atophan. The first patient was a man long suffering from gout rebellious to ordinary measures. Under a course of atophan he improved. A few months later the symptoms returned and atophan was prescribed again, when symptoms of acute intoxication developed, chills, fever, great depression and a red eruption on the head and neck resembling acute erysipelas, with extraordinary proportions of uric acid in the extremely scanty urine. A month later the same syndrome reappeared anew when he began to take atophan again. The man died a few months later of tuberculosis. The second patient was a young woman who was also improved by atophan after long suffering from pain in one wrist. The pain returning some months later, she took one tablet of atophan and at once developed acute intoxication like the syndrome described in the first patient, with intense pruritus, but no eruption or exceptional uric-acid output. Marañon attributed the symptoms to casual contamination of the atophan, but the same syndrome returned even more severe a few weeks later after taking a single tablet obtained from another source, other patients taking without reaction tablets from the same package. Oyarzabal has recently reported a similar case in a man long subject to gout who had previously improved under atophan but presented the signs of an acute intoxication after taking novatophan. The eczema-like dermatitis which developed in this case proved very rebellious. This man had had dermatitis develop years before when a skin affection was being treated with formaldehyd.

Medicolegal

Law Requiring Washrooms for Employees Constitutional

(People vs. Solomon (Ill.), 106 N. E. R. 458)

The Supreme Court of Illinois holds constitutional an act to provide for washrooms in certain employments to protect the health of employees and secure public comfort, approved June 26, 1913. The court held that a similar act passed in 1903, which applied only to the owners or operators of coal mines, was unconstitutional on the ground that it was special or class legislation; that the legislature could not require the owners or operators of coal mines only to provide and maintain washrooms for their employees, for the reason that such a law would place on mine owners or operators a burden not borne by other employers of labor, and such enactment would be special legislation. Any act of this kind, to be valid, must apply to all employers of labor similarly situated or to all employers of labor where conditions obtain which would require washrooms. This object was accomplished in the act of 1913 by naming in the first section of the act, specifically certain employments to which the act applies, namely, of every owner or operator of a coal mine, steel mill, foundry, machine shop, followed by the words, "or other like business in which employees become covered with grease, smoke, dust, grime and perspiration to such extent that to remain in such condition after leaving their work without washing and cleansing their bodies and changing their clothing, will endanger their health or make their condition offensive to the public." The purpose of the law is to promote the health and welfare of employees in certain lines of business where the conditions are such that every facility should be afforded for cleanliness, and to provide for the comfort and welfare of those with whom such employees come in contact after leaving their places of employment. The right of the general assembly to enact such laws is under the police power of the state. Nor, as the court construes this law, is it ambiguous and uncertain. It applies to the employments specifically mentioned in the act and to all other like business of permanent character where the same conditions prevail and where there would be the same reasons for the law to apply.

Liability for Wrongful Removal of Typhoid Fever Patient—Admissible Evidence

(Lynch vs. Rosemary Manufacturing Co. (N. C.), 83 S. E. R. 6)

The Supreme Court of North Carolina says that, the jury having accepted the plaintiff's version of the removal from one of the defendant's houses of his wife while sick in bed with typhoid fever, and having rendered a verdict that the defendant unlawfully and wrongfully caused her death, the court finds no good reason for disturbing their conclusion on the issue fixing liability on the company. But the court holds that there was error in an instruction as to the amount of damages, wherein the jury were told they *should* take all the evidence and say what the wife's earnings would have been during the balance of her life, and about how long they found she would have lived. The rule established by the decisions of this court for the admeasurement of the damages for this kind of an injury is that it is the present net value of the life which has been wrongfully taken. For that error the judgment in the plaintiff's favor for $2,500 is reversed and a new trial is granted on the issue as to damages.

It was urged for error that some of the expert witnesses were allowed to give it as their opinion that the removal was the cause of the wife's death, as it violated the rule that a witness may not express an opinion on the very question at issue between the parties. But the questions objected to were clearly within the rule for the reception of such evidence, being opinions of medical experts as to the cause of the patient's death, predicated on the symptoms of the patient and the attendant facts, assumed to have been found by the jury.

Nor does the court think that there was error in asking a medical witness, on cross-examination, if all recognized medical authorities do not teach that typhoid fever patients must not be moved, if possible to do without it, after the witness, who had treated the patient, had testified for the defendant in effect that the removal, in his opinion, "had not unfavorably affected the patient in this instance, and that, on the facts of the case, would likely increase her chances for recovery." It is very generally recognized that extracts from medical books are not admissible in evidence, and for the very sufficient reason that the author does not write under the sanction of an oath and has not been subjected to cross-examination. Moreover, the decisions of this state are to the effect that statements from these books may not be presented as such in the arguments of counsel nor introduced by means of questions put on cross-examination, as by reading an opposing opinion from a text-book and asking the witness "if it is or is not true." The principle, however, is not as exigent in case of cross-examination, and when a witness has testified as an expert, professing to have special training and knowledge from standard works of his profession, a general question of this kind may be allowed with a view of testing the value of his opinion.

Assured Having Had Other Complaints than One Causing Death

(Cunningham vs. Modern Brotherhood of America (Neb.), 148 N. W. R. 918)

The Supreme Court of Nebraska holds that where the assured, shortly prior to making his application for membership in the defendant association, was treated for catarrh in the head, and still prior to that time had been treated for lumbago or rheumatism in the back, but there was no evidence to show that the *particular disease which caused* his death had been contracted before the beneficiary certificate was issued, it would not be considered that an inquiry could be made as to whether the disease of which he died was latent in his body. The fact that he had other complaints than the particular one which caused his death placed the beneficiary under no obligation in case of suit to show that the assured was sound as to the particular complaint causing his death at the time that the certificate was issued and he was admitted to membership. In an action on a beneficiary certificate it is not proper to place the burden of proof on the beneficiary to show that, at the time the certificate was issued, the assured was free from the particular infirmity which ultimately caused his death. Persons engaged in a life insurance business should be required to take the risk that properly belongs to the business, and the right of the beneficiary to recover should not be made to depend on the skill, intelligence and accuracy of knowledge possessed by the assured touching his own physical condition.

Liability for Causing Malarial Fever

(Rice vs. Norfolk-Southern Railroad Co. (N. C.), 82 S. E. R. 1034)

The Supreme Court of North Carolina affirms a judgment in the plaintiff's favor for damages alleged to have been due to the defendant having negligently permitted one of its drains to become clogged, ponding water under the plaintiff's house, with the result, as witnesses testified, of causing his children, aged, respectively, 13, 15 and 18 years, to have malarial fever. The court says that there was evidence of the cost of the physician's bill and medicine and of the plaintiff's loss of the services of his children. There was also the testimony of the physician that the ponded water bred mosquitoes whose bite caused malaria. It is now the accepted doctrine of the medical profession that malaria is transmitted by the bite of a certain kind of mosquito, anopheles stegomyia, and that these mosquitoes are bred in standing water. True, counsel for the defendant expressed his belief that mosquitoes were *only bred* in running water, and doubted the correctness of the doctrine that malaria was transmitted by their bite; but there was the testimony of the physician to that effect, and the trial court properly left the matter, being one of fact on the testimony, to the jury. Indeed, there was no evidence to the contrary.

Experimental and Clinical Studies in Hemolytic Jaundice, with Special Reference to the Effects of Splenectomy

Dr. Edward B. Krumbhaar, Philadelphia: The experiments which Dr. Pearce, myself and our colleagues have been carrying on for the past three years, though at first concerned with the relation of the spleen to hemolytic jaundice, soon opened up to us the broader problem of the relation of the spleen to blood formation and destruction in general. Our first experiments confirmed and elaborated the earlier observations of Banti and Joannovics that it was more difficult to produce jaundice by means of hemolytic serum in splenectomized than in normal dogs. Attempts to explain the cause of this phenomenon, which was directly related to clinical splenectomy for the cure of various conditions associated with hemolytic jaundice, led us to study the blood changes following splenectomy. We found that anemia always developed, reached the maximum about the third week and dropped to normal in about ten months. Pearce, Karsner and Peet find that the resistance of the red cells is increased after splenectomy both to hypotonic salt solution and to immune serum. Austin noticed that the greatest resistance to jaundice occurred at the same time as the greatest anemia developed. I have found the same resistance and have concluded that the phenomena were partly due to the more resistant erythrocytes, and partly to the fact that less blood is destroyed because there is less blood to be destroyed. In testing the blood-forming powers of the spleen by making a comparison of the blood going to and coming from the organ, some authorities assert that they have found more red cells, white cells and hemoglobin in the splenic vein, but our experiments along these lines were negative and it seems that we must accept the dictum that red cells at least are formed only in the bone marrow. Asher and his pupils have offered as an explanation of the anemia following splenectomy that increased amounts of iron are lost through the stools, but here also our experiments have failed to confirm such an explanation. We found, however, that injection of splenic extracts intraperitoneally have a marked temporary effect in raising the erythrocyte count, the leukocytes and hemoglobin, which is presumably due to the stimulation of the bone marrow. A possible explanation of the anemia following splenectomy is, therefore, that the bone marrow is deprived of a stimulating hormone, and the explanation of the later recovery from the anemia may be found in that the lymph-nodes found enlarged after splenectomy have presumably taken over some of the function of the spleen. Although splenectomized dogs showed less tendency to jaundice when hemolytic agents were administered, nevertheless such agents caused a greater fall in the blood counts, a more lasting damage, and a greater fragility of the red cells than in normal dogs. Apparently the lessened tendency to jaundice is connected in some way with the anemia caused by splenectomy, while the lessened power to recover from the hemolytic anemia must be attributed to the loss of some specific substance from the spleen. Banti has shown evidence of special hemolytic activity of the splenic extracts and of dissociated hemoglobin in the splenic vein, but our observations have failed to substantiate these claims. The unsaturated fatty acids are well known as hemolytic agents and the lessened blood destruction after splenectomy may thus be explained.

A review of the history and a detailed description of the different types of primary splenomegaly with anemia, namely, Gaucher's, Banti's, von Jaksch's and the two types of hemolytic jaundice, the Hayem-Widal, or acquired form, and the Chauffard-Minkowski, or congenital or hereditary form, show that Gaucher's disease has but little in common with the other types of splenic anemia and though the negative character of the symptoms might cause it to be confused with Banti's disease, pathologic examination should admit of a proper differential diagnosis. Although the etiology of Banti's disease is unknown, evidence points to the close causative relationship of the spleen. One would not expect the removal of a largely fibrotic organ to be attended with marked somatic changes, and it is in the earlier stages of the disease that splenectomy has proved most beneficial. The acquired and congenital types of hemolytic jaundice with splenomegaly possess rather characteristic differences and I deem it advisable to follow the Continental custom and consider them as independent conditions. In the congenital type the resistance of the red blood cells to hypotonic salt solution is much diminished, and this furnishes a simple differential test according to the technic which we used.

The cardinal symptoms of these types of hemolytic jaundice with splenomegaly are a chronic enlargement of the spleen, existing with an acholuria, non-obstructive jaundice and anemia, frequently paroxysmal in character and varying in intensity. Increased blood destruction is indicated by increased urobilin in the urine, and various characteristic changes are found in the blood; the red cells show diminished resistance to hypotonic salt solution; there is an increased number of reticulated cells with vital staining, and in the acquired form the phenomenon of auto-agglutination of the red corpuscles. In the congenital form the subjects are more often icteric than sick, while the acquired form is usually ushered in by a definite attack of sickness, the anemia becomes more grave, and the patient is distinctly more anemic than jaundiced. The congenital form seems to be more of an inherited dystrophy of the hemopoietic system, rendering the red blood cells more easily destructible. We have collected reports of eight necropsies and seven splenectomies which showed chiefly congestion of the spleen, especially of the pulp cords, with increased pigment and macrophages. Since therapeutic measures have been so ineffectual, splenectomy seems to offer the most hope for improvement or cure and should be considered, with due regard to conservatism, in all these diseases in which there is evidence of increased blood destruction referable to the spleen. In early Banti's disease and hemolytic jaundice the results of splenectomy have been excellent. In pernicious anemia, although improvement has followed in some cases, the value of splenectomy is more dubious, and this grave operation should be tried only when the indications are clear and other methods have proved unavailable.

Occurrence and Significance of Melituria in Infants Suffering from Nutritional Disorders

Dr. Oscar M. Schloss, New York: Sugar which has been used in metabolism is carried by the general circulation, and it is obvious that sugar which appears in the urine is derived from the blood sugar. Normal blood sugar in infants ranges from 0.07 to 0.11 per cent., figures practically identical with those that obtain for adults. There is a tendency for the blood sugar to maintain a constant level, but striking changes may occur following the ingestion of carbohydrate food. There is often a definite increase in the blood sugar shortly after a meal which reaches its maximum in from one and one-half to two and one-half hours and then decreases. This increase may be effected by starch as well as sugar, though the increase is slower and to a lesser degree. Owing to this fact the blood used for examinations was withdrawn about three and one-half hours after a meal. There is a distinct relationship between increased blood sugar and melituria. As a rule a continued increase in blood sugar leads to an excretion of sugar in the urine, although this effect may not be immediate. Often the hyperglycemia precedes the melituria for some time. It seems safe to assume that hyperglycemia means a disturbance in the balance between mobilization and consumption of sugar and often signifies a decreased power of burning sugar, provided the patient is afebrile and the diet normal. Most of the early writers considered that the sugar found in the urine of infants suffering from gastro-enteric disorders was lactose derived from the food. Finkelstein and Meyer attached great importance to melituria in nutritional disorders. They divided the cases into two groups: 1. Those in which the appearance of lactose in the urine was considered as indicative of an intestinal lesion through which lactose was absorbed before it was split by the inverting enzymes of the intestinal secretion. 2. When galactose was found in the urine, and it was thought that the underlying cause was a diminished sugar tolerance, the liver probably being at fault.

Our work comprised the study of the blood and urine of 235 infants. The preliminary tests were made by the reagents of Benedict and Nylander, and if the reducing substance was present in sufficient quantity, tests were carried out to determine its nature. There were forty normal infants whose blood sugar ranged from 0.068 to 0.11 per cent. The remaining 195 cases represented nutritional disorders ranging from the milder disturbances to those of severe intoxication. For convenience the cases were divided into mild, moderate and severe. There was an association between the increased blood sugar and the presence of sugar in the urine. As a rule, the cases with melituria showed hyperglycemia. In most instances the percentage of sugar in the urine ranged from 0.05 to 0.1 per cent. In such cases a determination of the nature of the sugar with any degree of accuracy was impossible. In twenty-seven cases the urine at some time contained 1 per cent. or more of sugar and further tests were made to determine its nature. These examinations showed that the sugar was usually galactose or dextrose. Lactose occurred, but not alone, it being always associated with galactose.

The important facts brought out are, therefore: 1. Melituria is usually accompanied by an increase in blood sugar. 2. The sugar in the urine is a monosaccharid. This indicates that a gross lesion of the intestine is not a direct cause of the melituria, but rather that the direct cause is a lowered tolerance to sugar. Our test to determine this tolerance shows definitely that there is a lowered tolerance to sugar in the nutritional disorders.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA

Meeting held Nov. 4, 1914

The President, Dr. James C. Wilson, in the Chair

Pain and Tenderness in Diseases of Spinal Cord, and Their Surgical Treatment

Dr. Charles A. Elsberg, New York: Little attention has been given to the neural origin of abdominal pain. Operations have been performed for supposed gastric disease when the real trouble was gastric crises in the course of tabes. Two patients have been sent into my service with the diagnosis of acute appendicitis. In both instances the patients had Pott's disease with irritation of spinal nerve roots, and areas of skin and muscle tenderness in the right iliac region. I have records of three patients in whom various operations had been performed who were finally found to have a spinal tumor or a neuritis of the nerves of the cauda equina. Another patient operated on for supposed gangrene of the toes, with severe pain shooting down the leg, was finally relieved by an operation for spina bifida occulta. To understand the distribution of painful symptoms in the extremities it is of value to remember the anatomy of the spinal nerve roots. A tumor may press on some of the nerve bundles without compressing the entire spinal root. I removed an extramedullary tumor of the spinal cord between the seventh and eighth cervical segments in a case in which the first and for a long time only symptom was a painful pin and needle sensation in the index finger of the right hand. The tumor was found to have pressed on only the lower nerve root bundles of the seventh cervical posterior root. From several cases of this kind I feel justified in stating that of the nerve bundles that make up the seventh cervical posterior root, the lower supply the index finger and the upper the thumb. In my last hundred laminectomies for spinal disease I have performed six operations on patients who had been treated for long periods for abdominal symptoms. In every case of indefinite abdominal pain and tenderness it is advisable to make certain that we are not dealing with a cutaneous hypersensitiveness which so often simulates real abdominal tenderness.

DISCUSSION

Dr. Charles W. Burr: In a patient seen some years ago the only symptom present was diffuse pain in the right arm. Later there was slight wasting in the muscles around the thumb. The pain was later replaced by painful anesthesia accompanied by marked wasting and gradually increasing palsy in the whole arm. After some time death ensued and at post-mortem there was found in the cervical region a long flat growth that had entered the nerve roots, first the posterior, causing only pain and then the anterior, causing pain and wasting. Had we but known the cause of the trouble, operation would have saved the patient a great amount of pain and probably her life.

Dr. Charles H. Frazier: It is too commonly supposed that pain is a constant and conspicuous symptom of spinal tumor, referred to the peripheral distribution of the segment involved. A number of cases of spinal tumors have been observed in which throughout the course of the lesion there was absolutely no pain. The widely varying results of rhizotomy would seem to throw some doubt on the present conception of the pathways of afferent impulses, and suggest the possibility of the ventral roots having some part in the carrying of afferent impulses. Such a hypothesis has been already advanced by Kidd. Whenever possible a therapeutic test should be applied before operation in order to determine whether interruption of the sensory impulses does not relieve pain. Spiller's suggestion of resection of the anterolateral column of the cord is a most valuable one and appeals to me particularly in cases of uncontrollable pain of the lower extremities, and more especially, because the operation does not necessitate the removal of as many laminae of the spine as would be necessary to cut the required number of lumbar and sacral roots. In the limited number of root resections for pain in my clinic there have been no fatalities, but in a larger series, performed by a number of surgeons, the mortality rate has been estimated at 10 per cent. This is too high. The risks of the operation should be materially reduced. The low rate of mortality in my experience with laminectomy I attribute chiefly to intratracheal anesthesia and to the use of the stovain block.

Dr. Charles A. Elsberg: I am not very enthusiastic about cutting posterior spinal roots in the treatment of the crises of tabes. Professor Foerster states that the only way to get a fairly good result is by an enormous laminectomy, cutting from the fourth or fifth dorsal down to the twelfth, and that even then the result is not certain. I have seen temporary benefit from the injection of stovain into the spinal canal. Laminectomy is an operation in which the mortality should be very small and one which a surgeon after a little experience should be able to do easily. In ninety-eight successive cases we have had no mortality.

Pathology of Tabetic Ocular Palsies

Dr. William G. Spiller: The ocular palsies of tabes have been regarded by some investigators as nuclear in origin, and the syphilitic ocular palsies as of nerve origin. This view may be disputed. I have studied by microscopic serial sections a typical case of tabes with complete internal and external ophthalmoplegia. The ocular nerves and their

Experimental and Clinical Studies in Hemolytic Jaundice, with Special Reference to the Effects of Splenectomy

Dr. Edward B. Krumbhaar, Philadelphia: The experiments which Dr. Pearce, myself and our colleagues have been carrying on for the past three years, though at first concerned with the relation of the spleen to hemolytic jaundice, soon opened up to us the broader problem of the relation of the spleen to blood formation and destruction in general. Our first experiments confirmed and elaborated the earlier observations of Banti and Joannovics that it was more difficult to produce jaundice by means of hemolytic serum in splenectomized than in normal dogs. Attempts to explain the cause of this phenomenon, which was directly related to clinical splenectomy for the cure of various conditions associated with hemolytic jaundice, led us to study the blood changes following splenectomy. We found that anemia always developed, reached the maximum about the third week and dropped to normal in about ten months. Pearce, Karsner and Peet find that the resistance of the red cells is increased after splenectomy both to hypotonic salt solution and to immune serum. Austin noticed that the greatest resistance to jaundice occurred at the same time as the greatest anemia developed. I have found the same resistance and have concluded that the phenomena were partly due to the more resistant erythrocytes, and partly to the fact that less blood is destroyed because there is less blood to be destroyed. In testing the blood-forming powers of the spleen by making a comparison of the blood going to and coming from the organ, some authorities assert that they have found more red cells, white cells and hemoglobin in the splenic vein, but our experiments along these lines were negative and it seems that we must accept the dictum that red cells at least are formed only in the bone marrow. Asher and his pupils have offered as an explanation of the anemia following splenectomy that increased amounts of iron are lost through the stools, but here also our experiments have failed to confirm such an explanation. We found, however, that injection of splenic extracts intraperitoneally have a marked temporary effect in raising the erythrocyte count, the leukocytes and hemoglobin, which is presumably due to the stimulation of the bone marrow. A possible explanation of the anemia following splenectomy is, therefore, that the bone marrow is deprived of a stimulating hormone, and the explanation of the later recovery from the anemia may be found in that the lymph-nodes found enlarged after splenectomy have presumably taken over some of the function of the spleen. Although splenectomized dogs showed less tendency to jaundice when hemolytic agents were administered, nevertheless such agents caused a greater fall in the blood counts, a more lasting damage, and a greater fragility of the red cells than in normal dogs. Apparently the lessened tendency to jaundice is connected in some way with the anemia caused by splenectomy, while the lessened power to recover from the hemolytic anemia must be attributed to the loss of some specific substance from the spleen. Banti has shown evidence of special hemolytic activity of the splenic extracts and of dissociated hemoglobin in the splenic vein, but our observations have failed to substantiate these claims. The unsaturated fatty acids are well known as hemolytic agents and the lessened blood destruction after splenectomy may thus be explained.

A review of the history and a detailed description of the different types of primary splenomegaly with anemia, namely, Gaucher's, Banti's, von Jaksch's and the two types of hemolytic jaundice, the Hayem-Widal, or acquired form, and the Chauffard-Minkowski, or congenital or hereditary form, show that Gaucher's disease has but little in common with the other types of splenic anemia and though the negative character of the symptoms might cause it to be confused with Banti's disease, pathologic examination should admit of a proper differential diagnosis. Although the etiology of Banti's disease is unknown, evidence points to the close causative relationship of the spleen. One would not expect the removal of a largely fibrotic organ to be attended with marked somatic changes, and it is in the earlier stages of the disease that splenectomy has proved most beneficial. The acquired and congenital types of hemolytic jaundice with splenomegaly possess rather characteristic differences and I deem it advisable to follow the Continental custom and consider them as independent conditions. In the congenital type the resistance of the red blood cells to hypotonic salt solution is much diminished, and this furnishes a simple differential test according to the technic which we used.

The cardinal symptoms of these types of hemolytic jaundice with splenomegaly are a chronic enlargement of the spleen, existing with an acholuria, non-obstructive jaundice and anemia, frequently paroxysmal in character and varying in intensity. Increased blood destruction is indicated by increased urobilin in the urine, and various characteristic changes are found in the blood; the red cells show diminished resistance to hypotonic salt solution; there is an increased number of reticulated cells with vital staining, and in the acquired form the phenomenon of auto-agglutination of the red corpuscles. In the congenital form the subjects are more often icteric than sick, while the acquired form is usually ushered in by a definite attack of sickness, the anemia becomes more grave, and the patient is distinctly more anemic than jaundiced. The congenital form seems to be more of an inherited dystrophy of the hemopoietic system, rendering the red blood cells more easily destructible. We have collected reports of eight necropsies and seven splenectomies which showed chiefly congestion of the spleen, especially of the pulp cords, with increased pigment and macrophages. Since therapeutic measures have been so ineffectual, splenectomy seems to offer the most hope for improvement or cure and should be considered, with due regard to conservatism, in all these diseases in which there is evidence of increased blood destruction referable to the spleen. In early Banti's disease and hemolytic jaundice the results of splenectomy have been excellent. In pernicious anemia, although improvement has followed in some cases, the value of splenectomy is more dubious, and this grave operation should be tried only when the indications are clear and other methods have proved unavailable.

Occurrence and Significance of Melituria in Infants Suffering from Nutritional Disorders

Dr. Oscar M. Schloss, New York: Sugar which has been used in metabolism is carried by the general circulation, and it is obvious that sugar which appears in the urine is derived from the blood sugar. Normal blood sugar in infants ranges from 0.07 to 0.11 per cent., figures practically identical with those that obtain for adults. There is a tendency for the blood sugar to maintain a constant level, but striking changes may occur following the ingestion of carbohydrate food. There is often a definite increase in the blood sugar shortly after a meal which reaches its maximum in from one and one-half to two and one-half hours and then decreases. This increase may be effected by starch as well as sugar, though the increase is slower and to a lesser degree. Owing to this fact the blood used for examinations was withdrawn about three and one-half hours after a meal. There is a distinct relationship between increased blood sugar and melituria. As a rule a continued increase in blood sugar leads to an excretion of sugar in the urine, although this effect may not be immediate. Often the hyperglycemia precedes the melituria for some time. It seems safe to assume that hyperglycemia means a disturbance in the balance between mobilization and consumption of sugar and often signifies a decreased power of burning sugar, provided the patient is afebrile and the diet normal. Most of the early writers considered that the sugar found in the urine of infants suffering from gastro-enteric disorders was lactose derived from the food. Finkelstein and Meyer attached great importance to melituria in nutritional disorders. They divided the cases into two groups: 1. Those in which the appearance of lactose in the urine was considered as indicative of an intestinal lesion through which lactose was absorbed before it was split by the inverting enzymes of the intestinal secretion. 2. When galactose was found in the urine, and it was thought that the underlying cause was a diminished sugar tolerance, the liver probably being at fault.

Our work comprised the study of the blood and urine of 235 infants. The preliminary tests were made by the reagents of Benedict and Nylander, and if the reducing substance was present in sufficient quantity, tests were carried out to determine its nature. There were forty normal infants whose blood sugar ranged from 0.068 to 0.11 per cent. The remaining 195 cases represented nutritional disorders ranging from the milder disturbances to those of severe intoxication. For convenience the cases were divided into mild, moderate and severe. There was an association between the increased blood sugar and the presence of sugar in the urine. As a rule, the cases with melituria showed hyperglycemia. In most instances the percentage of sugar in the urine ranged from 0.05 to 0.1 per cent. In such cases a determination of the nature of the sugar with any degree of accuracy was impossible. In twenty-seven cases the urine at some time contained 1 per cent. or more of sugar and further tests were made to determine its nature. These examinations showed that the sugar was usually galactose or dextrose. Lactose occurred, but not alone, it being always associated with galactose.

The important facts brought out are, therefore: 1. Melituria is usually accompanied by an increase in blood sugar. 2. The sugar in the urine is a monosaccharid. This indicates that a gross lesion of the intestine is not a direct cause of the melituria, but rather that the direct cause is a lowered tolerance to sugar. Our test to determine this tolerance shows definitely that there is a lowered tolerance to sugar in the nutritional disorders.

Pain and Tenderness in Diseases of Spinal Cord, and Their Surgical Treatment

Dr. Charles A. Elsberg, New York: Little attention has been given to the neural origin of abdominal pain. Operations have been performed for supposed gastric disease when the real trouble was gastric crises in the course of tabes. Two patients have been sent into my service with the diagnosis of acute appendicitis. In both instances the patients had Pott's disease with irritation of spinal nerve roots, and areas of skin and muscle tenderness in the right iliac region. I have records of three patients in whom various operations had been performed who were finally found to have a spinal tumor or a neuritis of the nerves of the cauda equina. Another patient operated on for supposed gangrene of the toes, with severe pain shooting down the leg, was finally relieved by an operation for spina bifida occulta. To understand the distribution of painful symptoms in the extremities it is of value to remember the anatomy of the spinal nerve roots. A tumor may press on some of the nerve bundles without compressing the entire spinal root. I removed an extramedullary tumor of the spinal cord between the seventh and eighth cervical segments in a case in which the first and for a long time only symptom was a painful pin and needle sensation in the index finger of the right hand. The tumor was found to have pressed on only the lower nerve root bundles of the seventh cervical posterior root. From several cases of this kind I feel justified in stating that of the nerve bundles that make up the seventh cervical posterior root, the lower supply the index finger and the upper the thumb. In my last hundred laminectomies for spinal disease I have performed six operations on patients who had been treated for long periods for abdominal symptoms. In every case of indefinite abdominal pain and tenderness it is advisable to make certain that we are not dealing with a cutaneous hypersensitiveness which so often simulates real abdominal tenderness.

DISCUSSION

Dr. Charles W. Burr: In a patient seen some years ago the only symptom present was diffuse pain in the right arm. Later there was slight wasting in the muscles around the thumb. The pain was later replaced by painful anesthesia accompanied by marked wasting and gradually increasing palsy in the whole arm. After some time death ensued and at post-mortem there was found in the cervical region a long flat growth that had entered the nerve roots, first the posterior, causing only pain and then the anterior, causing pain and wasting. Had we but known the cause of the trouble, operation would have saved the patient a great amount of pain and probably her life.

Dr. Charles H. Frazier: It is too commonly supposed that pain is a constant and conspicuous symptom of spinal tumor, referred to the peripheral distribution of the segment involved. A number of cases of spinal tumors have been observed in which throughout the course of the lesion there was absolutely no pain. The widely varying results of rhizotomy would seem to throw some doubt on the present conception of the pathways of afferent impulses, and suggest the possibility of the ventral roots having some part in the carrying of afferent impulses. Such a hypothesis has been already advanced by Kidd. Whenever possible a therapeutic test should be applied before operation in order to determine whether interruption of the sensory impulses does not relieve pain. Spiller's suggestion of resection of the anterolateral column of the cord is a most valuable one and appeals to me particularly in cases of uncontrollable pain of the lower extremities, and more especially, because the operation does not necessitate the removal of as many laminae of the as would be necessary to cut the required number of and sacral roots. In the limited number of root re for pain in my clinic there have been no fatalities, a larger series, performed by a number of mortality rate has been estimated at 10 per cent. too high. The risks of the operation should be reduced. The low rate of mortality in my experi laminectomy I attribute chiefly to intratracheal an and to the use of the stovain block.

Dr. Charles A. Elsberg: I am not very enthusiast cutting posterior spinal roots in the treatment of th of tabes. Professor Foerster states that the only get a fairly good result is by an enormous l cutting from the fourth or fifth dorsal down to and that even then the result is not certain. I temporary benefit from the injection of stov spinal canal. Laminectomy is an operation mortality should be very small and one wh after a little experience should be able to ninety-eight successive cases we have had no

Pathology of Tabetic Ocular F

Dr. William G. Spiller: The ocular palsies been regarded by some investigators as nuclear the syphilitic ocular palsies as of nerve origin. may be disputed. I have studied by microscop tions a typical case of tabes with complete external ophthalmoplegia. The ocular nerves nuclei were much degenerated; there was considerable round cell infiltration of the pia, but one of the abducent nerves which was less degenerated than the other showed also less round cell infiltration within the nerve. Round cell infiltration is indicative of the intensity of the syphilitic process. This case would throw doubt on the view that tabetic ocular palsies are nuclear.

DISCUSSION

Dr. Charles K. Mills: It is not at all uncommon for the diplopia often present in early tabes to disappear rather quickly. This would not occur were the palsies due to nuclear degeneration.

Dr. Daniel J. McCarthy: I would ask Dr. Spiller whether in his opinion tabes still exists, or whether all cases of tabes should be grouped together as spinal syphilis. My feeling is that we have distinct cerebral syphilis which reacts to treatment. Apart from this, paresis and tabes do not react, and when once developed are practically incurable.

Dr. W. G. Spiller: We recognize tabes and paresis, but we must regard them as truly syphilitic diseases. Tabes is caused by the degeneration of the posterior roots from the syphilitic poison. There are cases in which a positive diagnosis between spinal syphilis and tabes cannot be made. There are also cases in which the diagnosis between cerebral syphilis and paresis cannot be made, and these cases show how close the connection between cerebrospinal syphilis and the so-called parasyphilitic diseases may be.

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

American Journal of Physiology, Baltimore

December, XXXVI, No. 1, pp. 1-76

1 *Effect of Temperature on Action of Thrombin and Antithrombin. W. H. Howell, Baltimore.
2 Orientation of Holothurian by Light. W. J. Crozier, Boston.
3 *Effect of Radiant Energy on Lens and Humors of Eye. W. E. Burge.
4 *Physiology of Stomach. A. B. Luckhardt and A. J. Carlson, Chicago.
5 *Secretory Innervation of Hypophysis. I. Rabens and J. Lifschitz, Chicago.
6 Studies of Autonomic Thresholds. W. L. Mendenhall, Boston.
7 Carotid Blood-Flow in Relation to Intra-Abdominal Pressure. R. Burton-Opitz, New York.

1. **Temperature Action on Thrombin and Antithrombin.**—At temperatures approximating the body-temperature, Howell states, the action of antithrombin is greatly augmented. It is probable that this action is of importance in insuring the fluidity of the circulating blood in animals like the mammals in which the content of antithrombin in the blood is small. The effect of high temperatures (60 to 100 C.) in weakening or destroying the action of thrombin is accelerated greatly by the presence of small amounts of neutral salts (NaCl).

3. **Effect of Radiant Energy on Eye.**—Burge summarizes his observation as follows:

> Radiation from a quartz mercury vapor lamp which is sufficiently intense to coagulate egg albumin, egg globulin, vitellin, serum albumin and serum globulin in one hour does not coagulate the protein of the normal lens or of the vitreous or aqueous humors and hence does not affect the transparency of these structures after a continuous exposure of 100 hours. The region of the ultraviolet spectrum effective in coagulating the egg white lies between 265 and 302 microns. The region most effective lies around 265 microns.
>
> The lens protein can be modified by solutions of calcium chlorid, magnesium chlorid sodium silicate or dextrose too weak of themselves to affect the transparency of the lens so that ultraviolet radiation can precipitate the modified lens protein and hence produce opacity of the lens. The effective region in case of modification of calcium chlorid is from 265 to 302 microns inclusive. The most effective region lies around 265 microns. Analyses of senile cataractous human lenses show that calcium, magnesium, and in lenses from India, silicates are greatly increased in this type of cataract. The assumption is made that the accumulation of these substances modifies the lens protein in such a way that the short waves of the spectrum can precipitate the *protein*, thus producing opacity or cataract. In the case of diabetic cataract the accumulation of sugar in the liquids of the body so modifies the lens protein that the short waves of the spectrum can produce opacity, hence the prevalence of cataract in this disease.
>
> The above named substances, which so alter the lens protein that the short waves can precipitate it, at the same time decrease the fluorescence of the lens. This suggests that there may be some relation between this latter property and the great resistanc of the normal lens protein to ultraviolet radiation. In looking for the cause of cataract it would seem that at least two factors are to be considered, the one, a modification of the lens protein, and the other, radiation of short wave lengths by which this modified protein can be coagulated. Radiation from the infrared, or the visible region of the spectrum cannot coagulate either the *modified* or the *unmodified* lens protein provided the coagulation due to heat be excluded.

4. **Physiology of Stomach.**—According to Luckhardt and Carlson blood from starving animals and animals in pancreatic diabetes transfused into normal animals acts as a temporary stimulus to the gastric hunger mechanism. Excessive hemorrhage is followed by a temporary augmentation of the gastric hunger contractions. Prolonged starvation, pancreatic diabetes and possibly excessive hemorrhage result in the increase of some substance or substances in the blood that act as stimuli to the gastric hunger mechanism.

5. **Secretory Innervation of Hypophysis.**—The results obtained by Rabens and Lifschitz go to show that the presence of secretory nerves governing the activity of the hypophysis cannot be demonstrated by the glycosuria or hyperglycemia methods. The glycosuria resulting from the stimulation of the superior cervical ganglia is undoubtedly due to the effects of prolonged anesthesia and not to an excessive activity of the hypophysis caused by stimulation of a secretory nervous pathway to the gland. The authors suggest that the nerve fibers to the hypophysis described by Dandy may be vasomotor nerve fibers. The fact that no vasomotor nerves have been conclusively demonstrated in the cranial cavity does not prove that such nerves are absent from a complex gland like the hypophysis. And the fact that the anterior lobe has a vastly richer nerve supply than the posterior lobe does not in the least prove that these nerves are of a secretory nature. Stimulation of the cervical sympathetic nerves while the animal is conscious and under physiologic conditions does not produce hyperglycemia, glycosuria or diuresis. In all cases in which the animal is subjected to a crucial operation and prolonged ether anesthesia, glycosuria appears whether or not the superior cervical ganglia are stimulated.

A similar glycosuria occurred when the animal was subjected to mere prolonged anesthesia without even exposing the nerves or ganglia. Subjection to prolonged anesthesia after exclusion of all possible downward impulses to the abdominal viscera through vagus reflexes, with or without stimulation of the ganglia, led to a similar glycosuria. The glycosuria of prolonged ether anesthesia runs a uniform course, the amount of sugar gradually rising to a maximum and then gradually declining. This course is not influenced by the stimulation of the cervical sympathetic nerves, or the superior cervical ganglia.

American Journal of Tropical Diseases and Preventive Medicine, New Orleans

November, II, No. 5, pp. 295-355

8 *Leprosy. Its Treatment in Philippine Islands by Hypodermic Use of Chaulmoogra Oil Mixture. V. G. Heiser, Manila.
9 *Bacteriemic Nature and Laboratory Diagnosis of Leprosy. D. Rivas and A. J. Smith, Philadelphia.
10 Mosquitoes and Sewage Disposal. F. Knab and A. Busck, Washington, D. C.

8. **Chaulmoogra Oil Mixture for Treatment of Leprosy.**—The mixture used in the cases cited by Heiser was prepared as follows: Chaulmoogra oil and camphorated oil, 60 c.c. each; resorcin 4 gm. Mix and dissolve with the aid of heat on a water bath and then filter. The injections were usually made at weekly intervals in ascending doses. The initial dose is 1 c.c. and this is increased to the point of tolerance. The object sought is so to regulate the dose as to prevent reactions of too violent a character. Heiser says that experience shows that this treatment gives more consistently favorable results than any other and it holds out the hope that further improvement may be brought about. It produces apparent

cures in some cases, causes great improvement in many others, and arrests the progress of the disease in almost every instance. He has at present over 20 patients who have become microscopically negative since they began the treatment. The treatment is apparently equally efficacious in all forms of the disease; that is, the tubercular or hypertrophic, the anesthetic and the mixed.

9. **Bacteriemic Nature and Laboratory Diagnosis of Lepra.**—In support of the bacteriemic nature of lepra, that is that *B. lepra* exists in the circulating blood, Rivas and Smith have the following evidence: 1. *B. lepra* is found in the blood collected from healthy parts of the skin which are apparently normal and from which the micro-organisms are usually absent on section. 2. By the acetic acid method, *B. lepra* either singly, in pairs, in masses or in bundles is detected in the venous blood. 3. The presence of *B. lepra* in the form of lepra cells or phagocytosed by endothelial cells and more especially by lymphocytes in the venous blood. And finally, they suggest that the apparent or actual growth (at least temporarily) of *B. lepra* in cultures made from the venous blood may be an indication of the resemblance of leprosy to other bacteriemic diseases.

19 Is Antagonistic Action of Salts Due to Oppositely Charged Ions? J. Loeb, New York.

14. **Gastric Stimulation by Water.**—The authors claim that water (ordinary or distilled), either cold (10.5 C.) or warm (50 C.) as small a volume as 50 c.c. is a very strong gastric stimulant and in certain instances yields an acidity of over 100 c.c. (N/10 NaOH to neutralize 100 c.c. of juice), in less than twenty minutes. In the average normal individual water produces fully as great a stimulation (as measured by acidity and enzyme values) as does an Ewald test meal, and the acidity values follow a similar type of curve. Identical volumes of water introduced into the stomach of the same man during the same afternoon yielded similar acidity values. Under all conditions the increased acidity following water stimulation is accompanied by increased peptic activity, although the two types of values do not necessarily run parallel.

It was impossible to demonstrate any latent period for the human gastric glands. Therefore a prolonged and spread contact with the stomach mucosa is not a necessary preliminary to stimulation, as Pawlow and others have claimed. The introduction of 100 c.c. of distilled water into a stomach made empty by lavage was followed by the removal of samples at one-minute intervals which showed total acidity values of 19.5, 26.0, 49.5, 63.5 and 79.5. In one experiment definite evidence was obtained that 500 c.c. of water left the stomach in ten to twenty minutes after its introduction. In a single instance a very pronounced continued digestive secretion was observed. At least 225 c.c. of gastric juice of relatively high acidity were secreted after an initial stimulus afforded by 50 c.c. of distilled water (50 C.). Since water stimulates the gastric glands to activity when no food is present in the stomach as well as when there is a digestive task to complete, it seems to the authors a waste of glandular energy to drink water between meals. It would seem that water could best further the digestive plan when taken with meals.

Journal of Experimental Medicine, Lancaster, Pa.

December, XX, No. 6, pp. 545-641

20 *Effect of Gentian Violet on Protozoa and on Tissues Growing in Vitro, with Especial Reference to Nucleus. D. G. Russell, New Haven, Conn.
21 *Effect of Various Tissue Extracts on Growth of Adult Mammalian Cells in Vitro. A. J. Walton, London.
22 *Experimental Typhoid Infection of Gall-Bladder in Rabbit. H. J. Nichols, Washington, D. C.
23 *Proteotoxins (Anaphylatoxins) and Virulence. H. Zinsser and J. G. Dwyer, New York.
24 *Method of Counting Actual Number of Purkinje Cells Present in a Given Area of Cerebellum and Its Application in Ten Clinical Cases. F. W. Hitchings, Cleveland.
25 Agglutination Phenomena in Lobar Pneumonia. H. T. Chickering, New York.
26 Successful Cultivation of Skin Epithelium of Adult Frog, Rana Pipiens. E. Uhlenhuth, New York.

20. **Effect of Gentian Violet on Protozoa.**—The fact that embryonic and adult tissue of the frog will grow in vitro in the presence of gentian violet of a far stronger dilution than that necessary to kill many bacteria, as determined by Russell, lends encouragement to efforts now being made by him to apply the observations on the bactericidal effect of gentian violet and allied stains to the treatment of disease. Moreover, the ability of growing cells to rid themselves of this dye would indicate that it may be possible to apply the dye to infected tissue and count on the cells to eliminate the material after its work had been done. In Russell's experiments, for example, successful tissue growths were obtained when gentian violet 1 to 20,000 were used, yet *Bacillus subtilis* will not grow in 1 to 100,000 dilution and grows very badly in 1 to 1,000,000 dilution.

21. **Growth of Adult Mammalian Cells in Vitro.**—Walton found that the majority of tissue extracts stimulate the growth of connective-tissue, but liver extract inhibits it. The extracts are to a certain extent specific in their action on the growth of parenchymatous cells. Some cells are stimulated by one extract and inhibited by another, and those extracts which inhibit one type of parenchymatous cell may stimulate another type. Homogenous and autogenous extracts are equally efficacious in their action on the growth of cells.

22. **Experimental Typhoid Infection of Gall-Bladder in Rabbit.**—The following subjects are considered by Nichols: (1) pathogenicity of a living sensitized vaccine, (2) pathogenicity of first transplant from a living sensitized vaccine, (3) the regular production of lesions, (4) the gall-bladder lesion as a test of immunity, (5) the curative effects of vaccines, and (6) the practical bearing of experimental work. Altogether, ninety-seven animals were used and forty gall-bladder lesions were observed.

Nichols states that Besredka's living sensitized vaccine, given intravenously, does not produce a typhoid lesion of the gall-bladder in the rabbit. The first transplant of this vaccine is capable of producing this lesion. Hence this vaccine is not entirely safe to handle. Regular infections of the gall-bladder have not been produced by carrying a known pathogenic strain on rabbit blood agar, by successive passage through animals, or by the use of freshly isolated strains. No evidence could be demonstrated in the rabbit of the immunity produced in man by vaccination with a whole killed vaccine. Vaccine treatment did not cure the gall-bladder lesions.

Nichols concludes that with the present methods of producing infections in the chimpanzee and the rabbit, neither of these animals is suitable for deciding the problems of the immunization of man by vaccines. These problems must be settled by actual experience with large numbers of men kept under close observation.

23. **Proteotoxins and Virulence.**—The experiments reported on by Zinsser and Dwyer show that proteotoxin (anaphylatoxin) produced with typhoid bacilli and active guinea-pig serum, by the general method of Friedberger, possesses aggressin-like action in that, when injected together with sublethal doses of bacteria, it renders them lethal. This action is not specific, since even when typhoid bacilli are used in its production, the proteotoxin possesses this property not only for typhoid bacilli, but for staphylococci and prodigiosus bacilli, the only other organisms with which the

vaccine to counteract the toxic influence. He cites a number of cases in which the operation caused the disappearance of sugar. A case in point is the following: The patient was a man, aged 53, suffering from gangrenous phimosis, and the surgeon was averse to operation owing to the presence of sugar in the urine. The history showed that during two years there had been increasing frequency of micturition and some loss of weight. Four days before the patient saw Tirard he had been markedly drowsy and had complained of parched mouth and dry tongue. Although the specific gravity when first examined was 1040, it speedily fell after the removal of large gangrenous sloughs, and within a month it was extremely difficult to obtain any reaction for sugar. The sugar ultimately disappeared until the patient had an attack of tonsillitis, when during the high temperature sugar was again found to be present for a short time.

Tirard urges that the adoption of this view should encourage greater readiness to remove gangrenous tissues at an early stage, and that operations of greater magnitude might well be reserved until the quick reduction of sugar has permitted greater liberality of diet.

12. **Treatment of Wounds in War.**—Cheyne points out that the chances of rendering a wound aseptic are comparatively small after twenty-four hours, and practically *nil* after forty-eight hours: indeed, after that time he would not make any attempt to disinfect the wound. If, therefore, the case does not come under treatment within twenty-four hours no one can blame the surgeon or any system of treatment for the septicity of the wound. The reasons given by Cheyne as to why practically all wounds in the present war become septic are: (1) because there is often long and unavoidable delay in collecting the wounded and commencing treatment; (2) because the wounds may be very large, complicated and almost impossible to disinfect thoroughly; and (3) because in a good many cases no attempt is made to disinfect these wounds, or if it is made it is utterly inefficient.

As to the period of time during which it is advisable to attempt disinfection of the wound, Cheyne's opinion is that it is only during the first twenty-four hours that it is at all likely that bacteria can be eradicated, and indeed after twelve hours the result is not at all certain. During the first twelve hours, however, the great majority of wounds, unless they are large and irregular or complicated with extensive comminution of bone, can, he says, be rendered aseptic quite readily and immediately, and if proper precautions are taken afterward will remain aseptic, and thus the troubles resulting from the primary soiling of the wound will be avoided. The first point is to kill not only actively growing bacteria, but also the spores of bacilli. Cheyne prefers phenol to iodin as an antiseptic because it dissolves in the natural oil of the skin and so can extend its antiseptic action down the hair follicles and the orifices of the sebaceous glands. If more than twenty-four or possibly forty-eight hours have elapsed since the infliction of the wound any attempt at general disinfection of the wound would be an injudicious and harmful procedure, and still more so if suppuration has begun. The skin should be cleansed and disinfected and if there is any earth or gross dirt still visible about the wound the tissues involved should be cut or clipped away and the raw surface daubed with phenol. Apart from this, which is only occasionally necessary, Cheyne emphasizes that the important point is to provide the freest possible escape for discharge, and in order to obtain this it is often necessary to enlarge the original openings and to make counter openings. Further, any foreign bodies which are readily accessible should be removed, but at this stage it is not advisable to open up fresh wounds in the deeper tissues in order to hunt for bullets or pieces of shell, for this merely exposes fresh tissues to infection unnecessarily before the body generally has developed its full resisting power. The actual drainage of the wounds must be carried out by the use of as large drainage tubes as can be introduced conveniently with holes of suitable size in their sides; when there are counter openings, pass the tube through from one opening to the other.

As regards dressings in these cases, Cheyne says, aseptic dressings are not only useless but injurious. The septic discharge soaks into them, and decomposes there, and the dressing simply becomes a septic poultice which poisons the wound. Antiseptic dressings are better. Cheyne uses cyanid gauze next the wound with salicylic wool outside. His experience is that it is best to lay only a few layers of antiseptic gauze over the wound to prevent it being soiled by the clothing or blankets, and to apply boracic fomentations and change them frequently. Wherever it is possible, however, in the case of large wounds and those involving bones or joints, constant irrigation with normal saline solution is by far the best method of treatment. The irrigation is at first continued day and night, but as the discharge gets less and the wound begins to heal, boracic fomentations may be substituted during the night, but the irrigation should be continued during the day till healing is nearly complete. Cases in which gangrenous processes set in, a water bath, frequently changed with a little iodin or permanganate of potash in the water is the best treatment.

As to the removal of the missile which has done the damage, if it is present in the main wound, or is doing harm by pressure or otherwise, it should be removed at once, but not uncommonly fragments of shell or bullets pass into the tissues for a considerable distance from the main wound, and if left alone may become encapsuled and not do any harm and the wound of entrance will heal quite well. Such fragments can be removed by a separate incision later. if necessary.

October 31, XLIV, No. 44, pp. 1377-1392

28 *Vaccine Therapy in Gonorrhea. (Kritisches zur Vakzinetherapie der Gonorrhoe, zugleich experimenteller Beitrag zur Begründung der "ableitenden" Therapie.) B. Bloch.

28. **Vaccine Therapy of Gonorrhea.**—Bloch has not had as good results with intramuscular vaccine therapy as some have reported, but his experience in forty cases seems to show that the intramuscular and subcutaneous methods have no untoward by-effects as a rule. Only a few instances of complications have been published in which the preceding vaccine therapy might be incriminated. In these cases epididymitis or salpingitis, keratitis, a rash, transient cerebral symptoms or parenchymatous nephritis, developed in one case each. Bloch administered the vaccine in a few cases by intravenous injection and the results surpassed his highest anticipations. The reaction was very severe, both local and general, but the rapid subsidence of the gonorrheal arthritis and epididymitis, mucosa processes and pros-

tatitis testified to the therapeutic influence of the procedure. The idea occurred to him that the intense reaction—rather than any specific influence—was responsible for the benefit. To test this he treated three other patients with unusually severe gonorrheal arthritis by intramuscular injections of antityphoid vaccine. The febrile reaction was followed by prompt subsidence of the joint symptoms and finally a complete cure. Bloch does not venture to generalize from these three cases, but he thinks they sustain Gerhardt's statements in regard to the possible favorable influence of intercurrent infectious diseases on the course of chronic affections. (Summarized in The Journal, 1912, lix, p. 2194.) Such experiences cast doubt on the specific nature of certain reactions; antibodies against both typhoid and gonococcus infection, for example, are liable to be generated together. It sustains the old theory of revulsion and counter-irritation and suggests an explanation for the benefit reported from tuberculin in various supposedly non-tuberculous diseases.

Deutsche medizinische Wochenschrift, Berlin

34 Technic for Taking Medical Photographs. (Zur Technik der medizinisch-photographischen Aufnahme.) A. E. Stein.

29. **Tetanus.**—Czerny states that half of all the wounds that come into his hands are the jagged tears made by shrapnel and that tetanus threatens to decimate these wounded. There were 29 cases at Heidelberg alone up to the end of September. The fine hospital trains which make such an imposing display at expositions are unable to care for even a tenth of the wounded in the present gigantic battles. The wounded have to be taken to the rear in freight trains that have brought horses and other supplies to the front. There is no time to clean them properly and Czerny urges that two or three empty cars be carried along so that these can be cleaned and the wounded then transferred to the cleaned ones on the trip. By such care during the transportation it may be possible to ward off tetanus. In September he had four cases of tetanus that had developed on the way although the journey lasted only two days, and now the distance to be covered sometimes requires an eight-day journey. He cites Larrey's observation during the Napoleon campaigns that sudden changes in temperature and bad conditions in regard to transportation increased the number of cases of tetanus, and Czerny adds that the recent cold and wet weather has probably contributed to the increasing prevalence of lockjaw.

In treatment he suggests that as the tetanus toxin is destroyed by heat, it might be possible to sterilize the wound with superheated air or diathermia. Iodoform and Peruvian balsam, he says, might likewise check the growth of the bacteria. He thinks that primary amputation should not be rejected so absolutely as is the rule now. Two of his tetanus patients recovered after amputation. A third died without the contemplated amputation and necropsy revealed that the limb had been shattered much more seriously than its aspect revealed. All wounds should be given preventive antitetanus serum treatment when tetanus is prevailing; he had a patient once who died of acute trismus the sixth day after he had scratched his nose on the thorn of a rose. The wounded should be protected against jars, drafts and nervous shocks. A preventive injection of antitetanus serum should be given the same day as the injury, especially if it is a shell wound. He reiterates that local muscular spasm in the vicinity of the wound is often the first sign of trouble.

30. **Subcutaneous Injection of Magnesium Sulphate.**—Falk anesthetized the spot first with subcutaneous injection of 2 or 3 c.c. of a 1 per cent. solution of novocain, and then injected the 30 per cent. solution of magnesium sulphate. With inadequate doses, the spasms were exaggerated. If they did not subside spontaneously, they were controlled with chloral or another injection of the sulphate. The dose had to be 5 or 6 gm. to show any effect in the mild and moderately severe cases. No injurious by-effects were observed with single doses of 9 gm. up to a daily dose of 24 gm. One patient had 20 gm. given for six days in succession with good effect. In the very severe cases it is well not to be too timid with the dosage. As much as 12 gm. was given at one time in some cases without apparent harm. Under the magnesium the spasms relaxed in about an hour so that the patient could be raised to a sitting position and fed. Mild doses of chloral and morphin were given with the magnesium at times, although it was constantly borne in mind that the action of other drugs superposed on the magnesium might further depress the respiration function. An average of three injections were made in the twenty-four hours, as the symptoms returned, when the patients complained that their chests felt tight or they could not swallow. This feeling of tightness in the chest was generally the precursor of severe convulsions, and hence it calls for vigorous dosage.

44 Gynecology and Psychiatry. B. S. Schultze.

40. **Ruptured Extra-Uterine Pregnancy.**—Even in acute cases of ruptured extra-uterine pregnancy some authors advise expectant treatment, for they hold that if the patient does not die immediately she is apt to survive without an operation, which is therefore unnecessary. Even among those who admit the advisability of operating there is a dispute as to whether it should be immediate or deferred. Many American physicians advocate the latter plan. Others hold that each case should be treated individually, which is equivalent to expectant treatment with later secondary operation. When it comes to the advanced cases, there are still more operators who advise late operation or none at all. Olow advises immediate operation as a rule in all cases. He holds that intraperitoneal hemorrhage from any cause requires an immediate operation. It is impossible to decide which cases will recover if left alone. The advocates of deferred operation do not wish to operate in shock, but he believes that shock in extra-uterine pregnancy is as a rule due to the anemia, and will, therefore, increase rather than decrease. In the advanced cases the patient is always in danger of renewed hemorrhage if the operation is not performed, and this danger more than offsets the advantage of waiting for recovery from the anemia of the first hemorrhage. To show the advantages of routine operating over individualistic treatment in advanced cases, he compares his sixty-four cases with those of Scanzoni, who advocates individualistic treatment. Comparison of the figures shows that the results of operation are fully as good with reference to life, capacity for work and for conception, etc., and much better with reference to the time required for recovery.

56 *Gunshot Aneurysms; Thirteen Cases. H. v. Haberer.
57 War Wounds of the Eyes. (Kriegsverwundungen des Auges.) S. Bernheimer.

55. **Gunshot Wounds of the Skull.**—Marburg and Ranzi conclude from their experience with thirty-three cases that operative treatment is required for wounds from bullets striking at a tangent if there is evidence that the bone has been depressed and there are clinical symptoms of irritation or functional deficit. Also in cases of direct penetrating wounds when the projectile is close to the surface. Deep-seated projectiles can also be removed if severe symptoms develop, but the outlook is not very promising. On the other hand, prolapse of brain tissue indicates a more severe and diffuse brain process, causing edema or swelling of brain tissue, and the prospects are so bad that operative intervention is not advisable as the trouble is too generalized.

56. **Gunshot Aneurysms.**—Von Haberer gives an illustrated report of thirteen cases of gunshot aneurysm and emphasizes the importance of waiting for the virulence of the germs to become attenuated when the traumatic aneurysm has become infected. He condemns any attempt to operate as long as there is the slightest discharge from the wound, unless one's hand is forced by serious symptoms. In two of his cases there were no signs of infection but the pain was so intense that he operated without further delay, during the first three weeks. In the four other non-infected cases he waited until the fifth or sixth week. In the infected cases, the course was more favorable in those operated on without too long delay, and he thinks that the technic is of greater moment than the interval since the development of the aneurysm. He exposes the artery above and throws a loop of thread around it, but does not apply a constricting band to shut off the circulation from the limb. With the loop of thread he is prepared for all contingencies and can shut off the flow of blood at will, while the retention of the circulation otherwise is a great advantage.

In some cases a peculiar contraction of the knee was the first sign to call attention to the popliteal aneurysm; in others isolated radial paralysis was the first symptom of an axillary aneurysm. In still other cases sensory disturbances gave the first warning. The aneurysm may not develop for some time after the wound. In several instances the men were taken from the train already started on their way back to the front, apparently entirely cured of their wound from a bullet passing through a limb or the axilla. All his patients promptly recovered after the operation, only one, in advanced sepsis when first seen, required amputation. In one case the bullet entered the cheek and passed out through the neck on the other side causing an aneurysm involving the internal carotid and the jugular vein. There was a tendency to paralysis on the side of the entrance of the bullet, but this gradually subsided after the operation.

62 Improved Staining Technic for Sections. (Le colorazioni su sezioni libere non sparaffinate.) E. L. Tocco.

58. **Traumatic Nervous and Mental Affections.**—Bianchi emphasizes the difference in the course of post-traumatic neuroses and psychoses according as the patient has a claim for an indemnity or not. When there is no question of an indemnity, he usually recovers promptly and completely, but when there is a claim for damages or a pension pending, this keeps alive the consciousness of the injury even in the most upright. Those inclined to malingering at first may actually convince themselves in time of the truth of their statements, and really develop the neurotic symptoms assumed at first.

59. **The Hypophysis Triad: Obesity, Genital Disturbances and Disease in the Pituitary Body.**—In the three cases related, a man of 26 and two women of 17 and 40, previously apparently normal, became obese during convalescence from pneumonia or typhoid, the weight rapidly increasing to actual pathologic proportions and menstruation ceasing. The clinical picture seemed to be the same as that described by Fröhlich as the adipose-genital hypophysis syndrome. No tumor can be detected in the pituitary region and the trouble seems to be the result of the toxic-infectious influences from the pneumonia or typhoid on the pituitary body, arresting or perverting the internal secretion of the posterior lobe. Cases are on record in which the morbid cause was apparently in the adrenals, the genital glands or the thyroid, but the pituitary body takes the lead in this respect. The cases described confirm anew the functional interaction or synergism between the pituitary body and the genital glands. In acromegaly (syndrome resulting from excessive hypophysis functioning) there are phenomena suggesting hyperfunctioning on the part of the genital glands, while in the above adipose-genital hypophysis syndrome, the trouble is due to deficient pituitary functioning. Degeneration or sclerosis from infectious-toxic influences is liable, as well as a tumor in the pituitary body, to induce the hypophysis triad syndrome. This assumption is sustained by the gradual retrogression of the obesity in the case of the older woman under systematic treatment with extract of the posterior lobe of the pituitary body. She lost weight rapidly and diuresis increased, but the arrested menstruation did not reappear. The two other cases date from the era before introduction of organotherapy.

60. **Diseases of the Blood-Producing Organs with Enlargement of the Spleen.**—This article is the eighth of a series of clinical lectures on this topic at the bedside of patients. Rummo takes up in turn the leukemias, Banti's disease and other affections involving the blood-producing organs, and discusses the differentiating points and the treatment.

64 *Enlarged Glands with Chronic Rheumatism of the Joints. (Om Svulst af Kubitalglandlerne ved Polyarthroitis chronica rheumatica.) V. Ellermann.

64. **Enlarged Glands with Chronic Joint Disease.**—Ellermann relates that he found the spleen and numerous lymph-glands enlarged in a case of subacute polyarthritis in a child in 1909, and since then he has systematically examined for enlarged glands all his patients with joint trouble. Excluding all dubious cases and those with venereal disease, tuberculosis and uricacidemia, he lists twenty-eight cases of rheumatism in the joints of nine months to seven years' duration. In 50 per cent. the cubital lymph-nodes were enlarged. In normal conditions these glands are not palpable, and they are seldom enlarged with other affections.

ORTHOPEDIC SURGERY

ITS SCOPE AND ITS FUTURE *

LEONARD W. ELY, M.D.

SAN FRANCISCO

The practice of medicine embraces all branches of the healing art, and has no natural boundaries within itself. No man or set of men can appropriate a portion of it, claim it as private property, and warn trespassers off. Medicine is like the surface of the earth; what belongs to one body of men to-day may belong to another to-morrow. The fit shall take what the unfit cannot hold. Constant change is the symbol of life, and distinguishes scientific from sectarian medicine.

Specialties spring up in answer to a demand for concentration, for no one man can cover the entire field. All knowledge that the student unearths becomes, not his property nor the property of those associated with him in a similar line of work, but the property of the entire medical profession.

So long as a specialty is contributing to the advancement of knowledge, it tends to hold its ground, and to advance its borders. When it stops, other specialties encroach on it. It must take up new ground to avoid absorption either piecemeal by other specialties, or bodily by general medicine and by general surgery. Such a change of ground we have witnessed recently in gynecology. Whether the gynecologists can maintain their new position remains to be seen. If they succeed to the field of abdominal surgery, they will succeed to it, not by claiming that they are entitled to it, but by demonstrating that they are best equipped to hold it. When in my childhood's happy days I would say to my esteemed parent that I was "entitled" to this or to that, he would answer: "My son, you are entitled to just what you can get."

Orthopedic surgery was born to a strenuous life, and has held its borders, never sharply defined, by constant struggle. Its right to the name of a specialty, as you know, is still disputed. It is not recognized generally in medical schools as worthy of a faculty chair, and in many large communities it is not represented exclusively. Its pioneers devoted themselves largely to perfection of mechanical devices, and to accumulation of clinical data, but this knowledge has been appropriated quite rightly by our confrères, who are capable of applying much of it reasonably well with the aid of a skilled mechanic. We have no exclusive title to it. It does not "belong" to us.

We cheerfully acknowledge the remarkable work of the early orthopedists, but we shall gain nothing by pointing back to it. Their deeds reflect no luster on us. To dwell on former greatness is a symptom of degeneracy.

No one can say what our future will be, but that we are in the midst of a change, not on the verge of one, is evident. See what even now is taking place within our ranks. Compare our programs with those of orthopedic meetings of twenty years ago. Work of most diverse kinds is laid before us, demanding recognition and giving an intimation of the modern conception of the scope of orthopedic surgery.

Some there are who maintain that what was good enough for our predecessors is good enough for us. While we may not agree with them unreservedly, it will be well not to neglect that line of endeavor which gave our specialty birth. We must remember, however, that this branch of our work is shrinking constantly. Pott's disease formerly "belonged" to us without question. Orthopedists devise operations for ankylosing the spine, and the general surgeon invades our field—a good example of the changing boundaries of medicine.

Many, imbued with the scientific spirit, and impatient of didactic statement, devote themselves to the task of proving what we are wont with great complacency to regard as established truth, and they maintain with some fervor that much of it is not only not established, but is not even true. We must listen to them, though their discoveries throw into the scrapheap the theories gained by years of hard work. By animal experimentation and by laboratory investigation they will put our knowledge of the diseases of the body framework on a sound basis. Here surely lies part of the work of orthopedic surgery in the future.

The specialty must be stripped of every rag of the garment of mysticism which so persistently clings to it.

Diseases of bones and of joints furnish many of the baffling problems of modern medicine. They affect tissues whose histology, physiology and pathology are almost unopened books. We cannot understand disease in tissues of whose structure and function we are ignorant. Here is a work to fire the imagination of the young. A few years spent in patient investigation may bring more lasting renown than a lifetime of clinical observation.

We have been too ready to draw conclusions without sufficient foundation of fact. One of the great needs in orthopedic surgery is the accumulation of solid facts.

Some diseases of bones and joints are said to "belong" to the general surgeon, others to the internist, but the field is open to all, and is almost unplowed.

---

* Chairman's address, read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, June, 1914.

A subject, until recently sadly neglected, now forces wide attention. I allude to fractures and dislocations. The general surgeon claims them. They are his if he can hold them. The orthopedist maintains that his mechanical training gives him greater skill in their management. He must demonstrate his skill: He has done so in some instances, notably in congenital dislocations and in certain fractures about the hip and shoulder. The vogue of open treatment of fractures may be interpreted as a reaction against the slipshod methods of the past. It will stimulate at least to more exact conservative treatment.

Functional disorders are becoming fewer in number as an organic base is found for many of them. Some orthopedists maintain that an error in mechanics of the body framework is responsible for certain of these diseases. Their views, while in many instances still largely theoretic, are worthy of a respectful hearing, but not, let me remind you, of acceptance until they are definitely proved. Let us beware the wiles of those brilliant men who urge us to cut loose from sound pathology and scientific proof, to follow them along the easy paths of attractive speculation. These paths lead to confusion.

In other instances an organic cause has been established. The orthopedic surgeon finds one for "idiopathic" sciatica and lumbago, and for intercostal neuralgia. Whose rights does he infringe thereby? Certainly not those of internist or neurologist.

Some regard orthopedic surgery as a narrow specialty. To me it appears potentially the broadest in medicine. These are but a few of the possible fields of activity. Orthopedic surgery is what we make it, and in brief includes everything that we can do better than others.

The future is in the hands of the younger men. Trained for scientific research as we never were, and starting where we finish, they shall climb the heights of knowledge which our feeble eyes see but dimly in the distance. Let us applaud bravely when they bring the structures which we have built up crashing about our ears. This is progress.

"Not as though I had already attained, either were already perfect; but I follow after——. I count not myself to have apprehended, but this one thing I do: Forgetting those things which are behind, and reaching forth unto those things which are before, I press toward the mark."

Lane Hospital.

Habit as a Pathological Factor.—The "bad habits" which are so characteristic of the various psychoneuroses may find their counterparts in perversions of the structural activities of the cells—that is, in bad habits of body (cachexias). Thus, for example, we find a tendency to the laying on of fat (lipomatosis, adiposis dolorosa, etc.)—i. e., to the formation of a tissue less highly organized than the normal—frequently associated with absence of the reproductive function (e. g., following the menopause, castration, etc.), The meaning of this is that function must go on somehow, and, in default of the "discontinuous growth" (reproduction) which normally succeeds ordinary "continuous" growth when maturity is reached, the individual, unless he has found some other active outlet for his energies, tends often, as the saying is, to "run to fat." Any one of the separate organs, also, which fails to express its normal capabilities is apt to begin to energize on a subnormal plane; witness *fibromyomas in the non-functioning uterus*. . . . A bodily habit, whether bad or good, is a group of cellular activities which have evolved together and grown into a complex which . . . is difficult to break up.—Arthur J. Brock, *Edinburgh Med. Jour.*

A PLEA FOR A MORE EXTENSIVE OPERATION IN CANCER OF THE BLADDER*

ARTHUR L. CHUTE, M.D.
BOSTON

After considering various subjects as possible topics for my address, I chose the one concerning which I really can give you fewest facts. I hope, however, that these few facts and the suggestions to which they give rise may arouse you to renew your attack on cancer of the bladder along lines that differ a little from those which we have in the main been following.

In my opinion there is no chapter in urinary surgery that is so absolutely discouraging as that which deals with our end-results—our so-called "cures" in cases of malignant disease of the bladder. I will grant you that our palliative treatment is very successful, that we make many of these sufferers very comfortable; but I feel that I am not ready to confess that we are reduced to nothing more than palliation in these cases.

If in any series of cases one mixes in a certain number of papillomatous cases—the large massive ones that have the appearance of a bladder tumor—one can get figures which are not absolutely discouraging. If, on the other hand, we deal with the carcinomatous growths that are primary in the bladder—squamous celled cancers, adenocarcinomas and the mucous cancers of the bladder, the growths which infiltrate and lead to metastases—our ultimate cures are almost none.

In the past few years we have increased very much the extent of our resections for malignant disease of the bladder and we have also made transplantation of the ureters relatively common, carrying out this maneuver whenever there was a reasonable question of the ureters coming into the diseased area. In spite of these more sweeping operations, I believe there is a very definite doubt whether our end-results are any better. Mine I am sure are not. I very much doubt if the number of permanent cures is at all proportionate to the increased immediate mortality of this more extensive operation.

This whole subject has come to me with particular force of late, as I have been studying up my cases of infiltrating bladder growths. I find records of twenty-nine cases, in eighteen of which operation was performed. Of these eighteen patients operated on, there was only one who was without signs of recurrence at the end of three years after operation. I am unable at the present moment to report on this patient's condition as I am not able to get into communication with him; but so far as I know he continues free from symptoms. There is another patient who has been operated on relatively recently, and I do not know that he has a recurrence; in fact, I believe he has not. All the others are either dead or have definite recurrences. I believe and hope that these figures are worse than the average, but fear they do not exaggerate the condition much.

It is wholly unnecessary, before this Section, to emphasize the importance of early diagnosis of cancer of the bladder, what its first symptoms are, and what its cystoscopic appearance is. Neither shall I deal with the technic of operation, but shall devote my time to a consideration of what I believe are certain basic principles in its treatment.

---

* Chairman's address, read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

In the study of my cases there came out certain facts, more or less disconnected, but that have, I think, a definite bearing on the question of the treatment of cancer of the bladder. In the first place, the one patient who has fulfilled the minimum arbitrary requirement that allows one to speak of cure in connection with cancer treated surgically—that is, the expiration of three years without signs of recurrence—was one of the patients whose operation was least extensive, though it was carried out about a month after the appearance of his first symptom, hematuria—the earliest case that has come under my care. This patient presented cystoscopically simply a little granular-looking area that was fairly widely removed laterally; it was not, however, very deeply removed. The incision went into the muscular layer only, not through it. Another important fact came out in the study of the condition found at the necropsy on one of my patients, who, a year before, had had a mucous cancer removed from the vertex of his bladder. This growth, including the full thickness of the bladder wall, was removed with a wide margin by the transperitoneal method. Though at operation I had been unable to find glands, at necropsy there were huge masses of retroperitoneal glands that were cancerous. More recently, I have chanced to notice in three other patients, on whom I did palliative operations, that the glands within the abdomen were involved.

It seems to me impossible to overestimate the importance of these two observations, illustrating (as I believe they do) fundamental points in the treatment of cancer of the bladder. The first, if I interpret it rightly, illustrates the fact that when a bladder growth is actually limited to the mucosa, we may excise it and have reasonable hope that there will be no recurrence. This depends on the generally accepted belief, which I believe is perfectly reasonable when we consider the storage function of the bladder, that its mucosa is either entirely without lymphatics or very poorly supplied with them, and that while a growth is actually confined to this layer there is nothing in the way of metastasis possible, the only extension being by continuity. The simple removal of a growth at this time destroys it *in toto*.

This accounts for what has been observed from time to time; namely, that freedom from recurrence has by no means been confined to the cases that have had wide removal of their growth; that it has appeared from time to time in patients whose growth has been excised with a very small area of healthy tissue. I believe that I am right in saying that in some of these cases, as in my own case, the microscopic examination left no doubt that the growth was really carcinoma.

Regarding the second point that I believe of importance—the finding of masses of carcinomatous abdominal glands at necropsy, and in three instances, of lesser glands at the time of operation—I believe that this illustrates at least one important route, probably *the* important route, by which these growths become disseminated. Though I felt no glands at the time I resected this man's bladder they may have been there at that time. Whether they were or not, I believe that this question of the lymphatics, both vessels and glands, is a most important one in the treatment of cancer of the bladder, one from which we may reasonably look for help.

In operations for cancer of the breast, tongue and stomach, and in the more modern methods of extirpation of the uterus and rectum, the lymphatic system is taken into very definite consideration and an attempt is made to remove diseased lymphatics and glands, with, so far as one can judge, improved results as regards cures. So important is this that it seems justifiable to increase the operative risk greatly in order to accomplish it. In cancer of the bladder, although we have had most disappointing results with present methods, we have simply widened our areas of resected bladder, still absolutely ignoring the possible part played by the lymphatics.

I think this is rather remarkable when we consider how essential a part of the plan of the modern surgical attack on malignant disease in other situations the tracing out of the course of the lymph-vessels has proved, and how carefully the removal of the diseased focus has been followed by the removal of the lymphatics and glands. I think at once of two possible reasons why this has not been done in cases of cancer of the bladder. One is the tradition that metastasis comes only late in these cases and that a dissection of the pelvic lymphatics would, therefore, be unnecessary. The other is that the operation would be so severe as to be impracticable in patients over 50—the age at which we see most cases of cancer of the bladder.

I am not ready to concede that this is necessarily so. I feel, however, that we should give this subject careful, attentive study in the hope that we may materially increase the number of patients who remain well following the removal of a cancer of the bladder. I am convinced that the most of our operating in this field is what one might fairly call "puttering"; we busy ourselves with little things and avoid great essentials. I feel that the removal of the lymphatics will be followed by better ultimate results than we now get.

Before an operation of this sort can be standardized it will be necessary to gain a wider knowledge of the lymphatics of the bladder than is generally possessed at present—whether or not different regions drain uniformly by the same channels. It will be necessary to find what cases it is useless to submit to so extensive a procedure. When this has been done, I believe that it will be found that a careful removal of the pelvic lymphatics will diminish the number of recurrences, much as seems to have taken place in the Wertheim operation for cancer of the uterus.

There is still another point that has a definite bearing on our method of operation. This is the fact that in ten out of twenty-nine cases the bladder growth had its seat so close to the bladder outlet as to make its local removal impossible without destroying the bladder outlet, in which case its total removal with the transplantation of the trigon and ureters would seem the rational procedure. I have always felt that total cystectomy was too fearful a mutilation to be often advised; yet if my series of cases is an average one, we must evidently advise it in one case in three if we are to remove the primary growth adequately—the first essential for successful treatment in all malignant disease. If in these cases the lymphatic current is found to be such that we can preserve that part of the trigon with the ureter openings and transplant it successfully into some part of the intestinal tract, preferably a part that has been shut off from the rest, to act as a new urinary bladder—if we can do this, the horror of total cystectomy will be materially lessened. Surgically there can be no question of the excellence of Watson's double lumbar nephrostomy as a preliminary to total cystectomy; personally, I feel I should not wish it. However, I think that unpleasant as total cystectomy is, we must expect to carry it out relatively frequently or else, because of inadequate removal of the local focus of disease, give up all hope of cure in a considerable proportion of cases of cancer of the bladder.

My contentions are that with every effort to recognize malignant disease of the bladder early, it will nevertheless be impossible to operate on more than an occasional patient when the disease is confined locally; in order to hope for better results in our treatment of cancer of the bladder, we must include as an essential part of our operation a dissection of the lymphatics of the pelvis; this must be done by routine, much as a dissection of the axilla is made in all breast cases except a few that are clearly too advanced to make this of advantage. When the local removal of the diseased area necessitates cystectomy, it must be carried out, or it is perfectly evident before we begin our operation that we shall fail in our object, that of stamping out the disease.

350 Marlboro Street.

SUBTOTAL CYSTECTOMY *

J. BENTLEY SQUIER, M.D.
Professor of Genito-Urinary Surgery, New York Post-Graduate School
NEW YORK

Cancer of the bladder constitutes 3 per cent. of all cancers in the male. Up to comparatively recent times we have had no adequate surgical technic for extirpation of malignancy in this organ. This is due to a number of factors, most important of which are: (1) the difficulty of conservation of the terminal ureters; (2) the lack of a definite surgical anatomy; (3) the questionable reparative power of the bladder, and (4) the hesitancy to attack the problem along definite surgical lines. An ideal extirpative operation for vesical neoplasm will be a technic which conserves or reconstructs the three natural orifices of the bladder, and one that removes the tumor *en masse,* with ileac adenectomy when the glands are involved.

In a consideration of this ideal operation there are certain facts to be thought of. It has been observed by a number of men and repeatedly demonstrated to me that if the three orifices of the bladder are conserved the bladder will regenerate and provide a functionating urinary receptacle. Another consideration is the desirability of a wide free exposure of the entire posterior surface of the bladder and base. Such a procedure may be accomplished either by transperitoneal dissection or as an entire extraperitoneal technic. In my earlier cases I regularly used a transperitoneal method but of late have carried out the technic entirely extraperitoneally. Where possible the anterior or pubovesical attachments are left intact. To meet the operative requirements both ureters must be constantly in sight; the lateral ileac extraperitoneal spaces readily available for exploration, and the entire bladder except the anterior portion freely mobilized. I believe that benign papilloma are at the present writing best treated by Oudin current. I believe that if any operative procedure is to be carried out for a vesical neoplasm, that neoplasm must be considered as actively or potentially malignant, and any operation for its removal must not be a simple excision but must be radical, along definite anatomic lines—in short, a *subtotal* cystectomy.

TECHNIC OF SUBTOTAL CYSTECTOMY

Description.—An operation for removal of a part or all of the bladder. Generally speaking, most operations involving the removal of a portion of the bladder are considered under the head of cystectomy, complete removal of the bladder being more in the nature of an operative curiosity than a feasible surgical procedure. The operative procedures may be carried out intraperitoneally or transperitoneally or as a straight extraperitoneal operation. It has been repeatedly observed that the bladder possesses wonderful reparative powers, and it has been demonstrated that from two-thirds to three-fourths of the bladder may be removed with subsequent adaptation to form an efficient urinary receptacle.

Incision.—This may be transverse or a median longitudinal incision (cystotomy). The longitudinal incision begins 1 inch above the navel on the left side and extends downward to the symphysis.

Step 1: The anterior sheath of the rectus muscle is divided about 1 cm. to the left of the mid-line and the left rectus displaced outward. The posterior sheath, above the semilunar fold of Douglas, is divided and the peritoneal fat exposed from the navel to the symphysis. By gently swabbing the fat and loose connective tissue up toward the navel, three important structures or surgical landmarks are brought into view. In the median line is found the urachus extending from the navel to the vesical apex. From the navel to each side of the urachus are found the obliterated hypogastric arteries, represented as divergent fibrous cords. These structures having been located, two procedures are in order: either to open the peritoneal cavity and continue the operation as a transperitoneal procedure, or to carry out the operation entirely as an extraperitoneal incision.

Step 2: The peritoneum is incised from the navel down to a point corresponding to the semilunar fold of Douglas. The patient is placed in an extreme Trendelenburg position and intestines gently deposited in the upper portion of the abdominal cavity. The pelvic cavity is thoroughly walled off by one or two long continuous rolls of sterile gauze. Two laparotomy pads are attached at each end of the wound in order to protect the incision from implantation of tumor cells.

Step 3: The urachus is grasped at the lower angle of the peritoneal incision by a Barret intestinal forceps. Traction is made upward, throwing into relief the obliterated hypogastric arteries as they divaricate to enter the true pelvis. The left obliterated hypogastric artery is grasped with forceps and traction made upward and to the right. By blunt dissection between the obliterated hypogastric artery and lateral wall of the pelvis, the left vas deferens is brought into view as it courses along the pelvic wall to the inner side of the obliterated hypogastric artery.

Step 4: A blunt single hook retractor is passed under the left vas deferens and gentle traction exerted. Blunt dissection is continued downward along the course of the vas deferens, and the pelvic ureter is uncovered as it bends inward above the fascia of the pelvic floor to enter the bladder, the ureter at this point being crossed on its inner side by the vas deferens. A similar exposure is made on the opposite side and the right ureter exposed. Any radical procedure directed to the extirpation of neoplasm of the bladder must have the two ureters exposed and constantly in view. This is the essential point in any radical technic.

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

Step 5: The urachus is divided close to the summit of the bladder and traction is made on the bladder downward toward the symphysis. From the two points of lateral dissection previously made the peritoneum is stripped off the fundal surface of the bladder. The denudation extends deep into the rectovesical space and the peritoneal culdesac of Douglas is pushed upward and backward. If the peritoneum is found firmly attached to the bladder and already the seat of malignant infiltration, this area is left undisturbed and a wide encircling incision made about the infiltrated peritoneum. If the peritoneum is not infiltrated, the entire bladder, except the anterior or pubovesical attachment should be freely mobilized, both ureters free, and the superior poles of the vesical and the upper portion of the posterior surface of the trigone in sight. The entire procedure can be carried out without entering the peritoneal cavity. Occasionally, the peritoneum is torn into and should be brought together with No. 1 plain catgut. No hemorrhage of any moment should have been encountered and the venous ooze should have been readily controlled by hot wet pads.

Step 6: The denuded lamella of peritoneum is carefully attached to the upper end of the abdominal incision, so that, for all further operative procedures, the peritoneal cavity is to all intents and purpose closed.

Step 7: The bladder is grasped high up on the posterior surface and an incision is made in the longitudinal direction, about 1 inch in length. Through this opening an inspection of the bladder is made and the topography of the tumor determined. The incision is extended in any direction that may be necessary for proper operative exposure. Since, in the majority of instances, the tumor will be found to occupy the summit, side or trigone of the bladder, an incision downward in the posterior median line, which splits the organ in half will be the usual incision of election.

Step 8: The neoplasm is excised *en masse,* together with a wide margin of healthy, uninvaded tissue comprising the entire thickness of the bladder wall. The exposure of the ureter, which has already been made, now becomes of prime importance. If the ureter is affected it is divided between the ligature above the growth and the distal portion is removed with the tumor. The proximal portion is allowed to remain undisturbed until partial closure of the bladder defect is accomplished.

Step 9: The hiatus of the bladder wall after excision of the tumor is partially repaired (the method of closure being similar to the Connell intestinal suture with No. 2 chromic gut), a stab-wound is made through the bladder wall at a point approximating the normal ureteral opening and the proximal portion of the divided ureter drawn through this opening by a thin dressing forceps.

Step 10: The ureter is brought through the stab-wound and anchored to the bladder wall. About ½ or ¾ inch of the ureter is allowed to protrude into the bladder. Two flaps are made by dissection of the ureteral stump and the flaps turned back and anchored *in situ.* The remaining defect in the bladder is closed with a Connell suture as above and drainage of the bladder instituted by means of a stab, button-hole incision, anterior to the line of incision and at a point that will correspond to the highest point of the bladder when the operation is completed. Through this aperture a No. 26 F. soft rubber catheter is drawn and sutured *in situ.* A drainage-tube inserted in this manner insures against leakage along the tube into the perivesical space.

Step 11: The final step is the reposition of the peritoneum over the vesical suture line and an accurate closure of the peritoneum. If the peritoneum is invaded by the growth, the involved portion is resected with the growth and the peritoneal hiatus closed after the usual fashion, particular care being taken to prevent a peritoneal suture line being superimposed on a bladder suture line. A cigarette drain is inserted into each lateral space leading down to the ureter and the abdomen closed with Figure 8 silkworm sutures. In addition, a self-retention catheter is inserted.

COMMENTS

The operative treatment of tumors of the bladder has been inadequate in preventing local recurrence and implantation metastases. In a case of malignant tumor, the tumor *per se* should not be handled and the excision must be through all the coats of the bladder and the peritoneum adjacent to the bladder wall if found to be infiltrated. The wide denudation in the preceding technic can be made with the patient in a high Trendelenburg position, either intraperitoneally or extraperitoneally.

The vas deferens in the male offers the most reliable and quickest way of reaching the terminal ureter. The blunt dissection along the lateral walls of the pelvis allows for the exploration about the ileac vessel for metastatic glands.

In the female the relation to the uterine artery allows for an accurate localization of the terminal ureter.

Any cystectomy for vesical tumor should be radical along the lines indicated above. In substance there is no difference between intraperitoneal and extraperitoneal surgery for this class of work. Leakage, if it does occur, does not take place into the peritoneal cavity when the peritoneum has been sutured carefully with a serous approximation of surfaces. If after opening the bladder a malignant neoplasm is excavated or sessile, cauterization of the base or surface of the tumor is a procedure of undoubted palliative value. After excision, searing the cut edges before suturing is a very wise precaution. The use of 50 per cent. resorcin or 1:5,000 mercuric chlorid, swabbed about the bladder, is useful in destroying any detached tumor particles.

49 East Forty-Ninth Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. CHUTE AND SQUIER

Dr. Eugene Fuller, New York: Cancer of the bladder has, as a rule, been treated in a very haphazard and unsatisfactory manner. Such work as Dr. Squier has shown is certainly beautiful. It gets down where the disease is in the cases that are so operable, and leaves practically nothing to chance. We have been inclined in most cases to rely on sparking and to sit back and do nothing else, which is a bad thing, although in certain cases the spark has done good and is the approved treatment. It is *only* in certain cases, however. I had one case in which I operated for cancer of the floor of the bladder, and the man was living ten years afterward. In that case I resected a large portion of the bladder. I made a suprapubic incision, transfixed the whole mass, took it out, and got a perfect result. Operating like that is more or less haphazard. Five years afterward I operated in this same case for a little recurrence in the stump, and took that out. It is advisable in these cases to operate radically. Again, there may be a case in which one thinks one has done radical work and is disappointed. Not long ago I had such a case in which I resected a considerable portion of the bladder. The man, I thought, was doing extremely well; he got up; but five weeks after the operation he had a spontaneous fracture of the upper thigh from metastasis. I do not think we could manage radically cases like that which Dr. Squier reported, except by the careful method which he described.

Dr. John L. Atlee, Lancaster, Pa.: I report two cases with a great deal of reluctance. I had, recently, two cases of cancer of the bladder in which I did a total extirpation. The first one I did simply because I did not know what else to do. The man had a cancer in the location shown by Dr. Squier, I would say, possibly half again as large. In the cases that I had seen in which no attempt had been made to relieve, the patients had suffered so that I felt I was justified in making the attempt. In that case I did a total extirpation, simply skinning the bladder from the prostate. The ureters were stitched together where they crossed the rectum and were transplanted together like the barrels of a double-barreled gun. The abdomen was drained, and a large rubber tube placed in the rectum. That man is 52 years old. There was very little shock. His recovery was very satisfactory. The control of his rectum was very satisfactory. He also had satisfactory sexual intercourse. He lived nine months and died from recurrence. He had pain in the region of the kidney, which I thought was due to an ascending infection, but at necropsy the glands were involved all over that side, and I felt that the pain was more due to the glands than to an ascending infection. Both ureters were full of turbid urine, and there was no evidence that I could see of an ascending nephritis. The second patient was operated on about two months later, about eight months ago. The man was 63 years old. The operation was done the same way, except that the ureters were cut higher up, and the left ureter was stitched into the sigmoid. That man is still alive, although he does not look well. He had one attack of ascending infection on the left side, with pain and rise of temperature, but he recovered. He was feeling well when I saw him three weeks ago, but he does not impress one as being a healthy man.

As I said, I did these operations with, possibly, no justification except to try to save the patients from a terrible death. If the lymphatic drainage of the bladder is as free as some authorities claim, that is, not only into the pelvic glands, but also into the inguinal glands and into the saphenous glands, a block dissection of the bladder is impossible. Therefore, if a block dissection is necessary it would be impossible in the bladder, because it is difficult enough in the Wertheim operation. If we applied it as a palliative operation the chance is that the patient would die as soon from infection as he would have died from metastasis. I was surprised at the comfort these men had in passing the urine from the rectum. They would go all night without urinating. One of the men was strong enough to go back to work, but did not have to do so. Both men expressed themselves as perfectly satisfied with that method of voiding urine.

Dr. Francis R. Hagner, Washington: The point Dr. Squier makes about getting at the ureter first and separating the bladder afterward, simplifies the operation very much. I have not done this operation by his method, but I have taken calculi out of the ureter by the same method. It is possible to get a better exposure than in any other way I know of. Dr. Chute has spoken of infection of the glands in these patients. Any one operating on such a patient and seeing large glands would remove them. It is a question whether it would do any good. We know the glands are not involved until late in the disease, and I have seen necropsies on such patients in which there was no involvement of the glands. Some years ago I presented a method of operating on growths of the fundus and lateral walls of the bladder by cystoscoping the patient, and under visual inspection outlining the growth with traction sutures. One of the weak points in the removal of growths from the bladder is the traumatism to the growth, and by this method it is easy to remove them without traumatism. One patient was operated on four years ago and has had no recurrence; one over three years ago, with no recurrence, and another died recently from some intercurrent trouble with no evidence of recurrence.

Dr. R. L. Rigdon, San Francisco: What would Drs. Squier and Chute do in such an instance as this? Just before leaving home I examined a patient who presented a well-defined, rather small tumor, occupying the right side of the bladder, including the bladder neck, apparently taking in the urethral orifice. Let us take it for granted that from a general point of view that man is suitable to be operated on. Whether or not the ureter is involved does not seem to make much difference because we can transplant that; but when I go back home what shall I do for that man? If I operate on him I must remove the sphincter of the bladder, at least a portion of it. I was in hopes that some of our members would report a brilliant series of cases treated by means of the spark so that I might be saved the necessity of doing a more radical operation on that patient.

Dr. B. A. Thomas, Philadelphia: The rationale of the extraperitoneal and the transperitoneal route of approach in these cases with the partial excision of the bladder described by Dr. Squier is certainly the most valuable suggestion which has yet been offered in cases of cancer. I strongly believe that the method *par excellence* for treatment of papillomas of the bladder, whether single or multiple, is the method of high-frequency desiccation or sparking by the Oudin high-frequency current, and I have treated no less than thirty tumors in this manner, with very excellent results. How does Dr. Squier distinguish between carcinoma and papilloma? I think the impression that he desires to make is that this operative method is applied only in undoubted cancer of the bladder, but I would enjoin the importance of this differentiation, in view of the superior advantage of the electric-spark treatment in cases of papillomas. We all know that in papillomas there may be two sites at which epithelial degeneration and cancerous formation take place; these are, superficially and at the pedicle attachment with the bladder-wall. Even though the surface of the growth is cancerous, the pedicle may not be, and one can cure such epithelial superficially degenerated tumors, if one is able to make the differentiation, by the high-frequency spark. On the other hand, if there be cancerous degeneration of the pedicle, the only method of treatment is that which has been described by Dr. Squier.

Dr. Louis E. Schmidt, Chicago: I am in accord with Dr. Squier's statement that one should start out intelligently. In other words, the diagnosis must be accurate as to the location and extent. If a tumor is located on the left side of the bladder it would be rather unnecessary so far as his procedure is concerned, to separate the right side of the bladder completely, because, with a thorough understanding as to the location, the parts can be separated as was shown. I am in the habit of avoiding the intraperitoneal operation. If the tumor is located low down, not involving the ureter, I do not do the so-called Watson or intraperitoneal operation. I separate the peritoneum sufficiently far from the tumor, and if I see that the peritoneum is adherent it is then opened up sufficiently distant and can then be closed before the tumor is excised. One of the mistakes frequently made—at least I have seen it and have made it myself—is to distend the bladder to such an extent that the bladder-wall is of paper thinness. By so doing you easily rupture the bladder when stripping off the peritoneum. I prefer not to distend the bladder to any extent, and the procedure can be carried out as Dr. Squier has described it. I do not believe that the extent of bladder tumors plays such an important part in the prognosis, although we have always been told that the larger the tumor the greater the possibility of metastasis, particularly glandular. I operated nine years ago for a spindle-celled sarcoma, which is fairly malignant I think we will agree, when the entire bladder except the trigon was removed. This individual now has a bladder which is absolutely not to be recognized from any other bladder. He can hold his urine from eight to twelve hours, and has absolutely no vesical symptoms. In the past two months I have operated on him for an inguinal hernia. In this person there was certainly no glandular involvement. I have cases of resection of the bladder for cancer in which operation was done seven years ago with transplantation of the ureter. I have several cases in which resection of the bladder was done four or five years ago when a part of the trigon was removed, with a fair-sized portion of the posterior wall of the bladder. If, in those instances, there had been any marked metastasis in the glands, four or five years is a fairly long time, though it does not absolutely exclude the possibility that these individuals may die of cancer. In the last six months I have made three extensive operations for cancer, and the patients are still living. In opening the abdomen, however, it is well worth while always to examine for glandular enlargement. I believe that if enlarged glands are found it is almost a hopeless proposition. So far as resection of the neck of the bladder is concerned, I think many patients who have been operated on will be relegated to a different field of therapy.

Dr. Granville MacGowan, Los Angeles: The character of most of these tumors can be fairly differentiated by the careful use of the cystoscope. I do not use the high-frequency current for sparking a tumor that looks at all suspicious. If it is frankly a papilloma, it can usually be destroyed by the high-frequency current unless situated just above the bladder neck where they are difficult to get at. If a tumor is sessile or manifestly indurated, I consider it a cancer and regard as foolish the application to it of any mode of electricity or cautery except through a suprapubic incision. One must remove more of the bladder than just enough to get whatever is manifestly cancerous. I deprecate the use of the knife or scissors. There are electric cautery points made from iridoplatinum that are extremely efficient, easy to manipulate and allowing rapid work. After the removal of the tumor, any bleeding vessels should be ligated. I have had extremely satisfactory results with resection by the electric cautery, when not more than one-half of the bladder surface was included in the growth. I operated on one woman in 1900 for a cancer by this method, who was well until 1906 when another cancer appeared in an entirely different portion of the bladder. This was removed in the same way and she was well until 1911 but died in 1913 of cancer of the bladder. From 1906 I used the cystoscope on this patient two or three times a year and she had no cancer until 1911. With regard to Dr. Rigdon's case, if the cancer is situated on the vesical neck and it is hopeless to attempt to excise it without taking away the neck, I would not be deterred by regard for the internal sphincter, because I have removed bladder necks in operations for cancer of the prostate, with after results showing that the internal sphincter is negligable with reference to the retention of urine. In such a case the most reasonable thing to do is to side-track the bladder. If the bladder were removed as a receptacle for the urine by such an operation as was done by Dr. Atlee, I think it would solve the problem. I object to the use of the knife in cancer, because if a metastasis has not already taken place, it is easy to cause one by squeezing some of the cancer-cells into the open blood-vessels or the lymph-channels. The cautery seals up both blood-vessels and lymph-spaces. The cautery provides against the carelessness of one's assistant and of one's self. The cautery will cut, if you have the right kind.

Dr. William E. Lower, Cleveland: This is one of the most important unsolved problems that we have in genito-urinary surgery. Many of the operations on other parts of the genito-urinary tract are being more or less standardized, but this is an extremely annoying one, at least it is to me, and as Dr. Chute has stated, it is an operation that one does not expect very much from, but sometimes the results are surprising, showing a resistance to a particular kind of growth perhaps, rather than to any particular kind of operation. I think we make one mistake in these cases in not requiring our patients to come back for inspection as often as they should; after operation for cancer of the breast the surgeon asks his patient to report every three months. We wait until they have symptoms. If the patients come back every three months as I am having them do now, and we use a cystoscope, we can discover a recurrence, if any appears, fairly early, and at a time when remedial measures may be used, but if we wait for such objective symptoms as hemorrhage, etc., it may be too late. I recall one case that I reported before, in which I removed the tumor suprapubically by excision, and in less than four months it recurred. By the judicious application of the spark I have been able to keep the patient perfectly well now over three years. It was not a radical operation. In another case in which we did a radical operation we found that metastasis had already occurred and the patient was dying from metastasis in the bones. I am hopeful that this problem will be worked out in some way, because, as it is now, it is most discouraging and most unsatisfactory to be obliged to give the present results of operation for malignant tumors of the bladder to a patient presenting himself with such a lesion.

Dr. Martin Krotoszyner, San Francisco: The rapidity with which malignant bladder growths will occasionally recur and increase in size was made manifest to me recently in the case of a woman of 41 in whom a portion of the bladder had been resected for carcinoma. A few months afer this operation a careful cystoscopic examination revealed a normal bladder, but about two months later a large mass was seen to occupy the whole left side of the viscus. Since the patient refused any operative interference, I proceeded to fulgurate the neoplasm and the rapidity of the onslaught of the malignant infiltration became manifest through the fact that from one week's sitting to the next, new growth of carcinomatous tissue became visible within the fulgurated area. This case was to me another proof of the futility of treating malignant bladder-growths with the spark.

Dr. J. Bentley Squier, New York: With regard to the differential diagnosis referred to by Dr. Thomas, I simply state that the majority of vesical tumors are potentially malignant, if not clinically so, at the time we see them. I believe that one should not spend too much time in experimenting with the high-frequency current on any tumor unless there are unmistakable signs of improvement at once. Otherwise, get busy and operate. I think we will all agree with that. I have never had the opportunity to try Dr. Hagner's operation. It would strike me as being the ideal radical operation on a cancer, if one could outline the extent of the tumor beyond any question of doubt before extirpation is attempted, and I would recommend it as a wonderful operation for carcinoma situated in the vertex of the bladder. Dr. Schmidt asserts that one should make a correct diagnosis of the extent of the tumor by the cystoscope. I do not believe one can make an absolutely accurate diagnosis as to the extent of a vesical tumor by means of a cystoscope.

Dr. Schmidt: I said as nearly as possible. I said the location, not the extent, because I do not believe we can look through the bladder wall.

Dr. Squier: He says he should not open both lateral perivesical spaces because if the tumor is situated on one side one can locate it without so doing.

Dr. Schmidt: I mean that when the tumor is on one side of the bladder it is not necessary to peel the entire bladder out. One can feel the extent of the tumor. I think anybody who has done any surgery of the bladder will agree with me.

Dr. Squier: Dr. Schmidt is correct. I think that by the use of the cystoscope one cannot tell how much of the bladder-wall is involved in carcinoma. Therefore I believe that a general mobilization of the bladder gives one a greater ability to handle it correctly, Dr. Schmidt's criticism to the contrary notwithstanding. With regard to Dr. MacGowan's statement that he would not operate on these cases until they are ready to go to the grave—

Dr. MacGowan: I didn't say that. I said unless I could circumscribe the growth I did not care to operate.

Dr. Squier: My criticism of your remark would be the same. I defy you to outline it through the cystoscope.

Dr. MacGowan: I did not mean through the cystoscope.

Dr. Squier: What other criterion have you?

Dr. MacGowan: That was with reference to high frequency and the differentiation of a tumor that was manifestly a papilloma and one suspiciously a cancer. I would use high frequency on all those that clearly appear to be papillomas, and on account of the superficial action of the high-frequency spark I would not tease anything that looked as if it might be a cancer. I would either leave them alone if too extensive or if there were too large a number of them, or operate on them by the galvanocautery.

Dr. Squier: I am glad Dr. MacGowan has made his meaning clear. With regard to the knife or cautery, one is not cutting the cancer with the knife. Therefore, what is the objection to it? One is cutting the healthy bladder wall. Dr. Lower really voiced what I had in mind. It was not to describe any operation for carcinoma of the bladder which I thought would work in every case. I know in how many of my own cases it will not work, because I have tried it and I know exactly the results it will produce. I merely offered it so that some of us would go home and evolve a technic which would do something. We have sat back long enough and opened bladders and sent the patients home and have not given the patient a chance for his life. He is worse off than before. We have stimulated the cancer and given the patient a suprapubic fistula in many cases, and instead of being only unfortunate we have made him a nuisance to the community by making him smell of urine all the time. Let us do something definite or not do anything. The only criticism I would have is this, that if one is going to do a considerable resection of the bladder and depend on the line of sutures to prevent leakage into the perivesical space and possibly into the peritoneal cavity, the chance of primary union would be infinitely better following the use of the knife than the use of the cautery.

Dr. MacGowan: One can freshen the edges afterward and then put in the sutures and it will result in perfect union.

Dr. Squier: I do not question whether it is possible, but whether it would happen often enough to make it desirable.

Dr. A. L. Chute, Boston: There is little to be said concerning Dr. Rigdon's case. If you are going to give the patient a chance to be permanently well, all the malignant disease locally must be removed, including, in this instance, the bladder outlet. I see nothing to do but to perform a cystectomy, treating the ureters as seems best.

Surplus Energy and Progressive Evolution.—It appears to me that this power of profiting by experience lies at the root of our problem, and that in it we find a chief cause of progressive evolution. Jennings speaks of the principle involved here as the "Law of the readier resolution of physiological states after repetition," and, similarly, I think we must recognize a law of the accumulation of surplus energy as resulting therefrom. Let us look at the case of the accumulation of food-yolk by the egg-cell a little more closely from this point of view. Every cell takes in a certain amount of potential energy in the form of food for its own use. If it leads an active life, either as an independent organism or as a constituent part of an organism, it may expend by far the greater part, possibly even the whole, of that energy upon its own requirements, but usually something is left over to be handed down to its immediate descendents. If, on the other hand, the cell exhibits very little activity and expends very little energy, while placed in an environment in which food is abundant, it will tend to accumulate surplus energy in excess of its own needs.—Arthur Dendy, *Medical Journal of Australia.*

CERTAIN MINUTE CYSTS OF THE METACARPAL BONES FOLLOWING TRAUMA, AND THEIR CLINICAL RECOGNITION

P. G. SKILLERN, Jr., M.D.
Instructor in Anatomy and Surgery, University of Pennsylvania
PHILADELPHIA

While cysts of the long bones are not infrequently encountered, yet those involving the short bones of the extremities have received little or no attention. I have recently met two examples of pea-sized cysts situated, respectively, in the head and the base of a metacarpal. Both of these immediately followed trauma (contusion of bone); by reason of persistent pain and "wincing" tenderness both would have passed for subperiosteal fracture, although there was no swelling or ecchymosis; there was no enlargement of the bone, and there were no signs of inflammation. It was only by close scrutiny of the roentgenograms that the faint outline of each cyst was detected. Operation gave immediate and complete relief in both cases.

Case 1.—Miss M. J., aged 61, cook, reported at the Surgical Outpatient Department of the University Hospital (Case Record 40013) March 11, 1914, with the history of an injury, incurred sixteen months previously, to the base of the first metacarpal bone of the right hand. Since then there has been pain, which has gradually increased in severity. Clinically, there was localized tenderness similar to that elicited in fracture, but not quite so severe or "wincing." There were no other signs of inflammation. A roentgenogram revealed a cavity the size of a pea at the ulnar corner of the base of the first metacarpal bone. Under nitrous oxid anesthesia an incision was made along the ulnar border of the base of the metacarpal bone. The tendon of the extensor pollicis longus and the carpometacarpal joint, which were hard by, being carefully avoided, the cavity was readily entered with a narrow chisel, and was curetted. It was packed with iodoform gauze, and a dressing and a splint were applied. On her return the next day the patient stated that she had been free from the boring pain for the first time in sixteen months. On discharge, two weeks later, the wound was all but healed.

Case 2.—Mr. J. W., aged 33, machinist, reported at the Surgical Outpatient Department of the University Hospital (Case Record 40893) June 18, 1914, with the history of an injury, inflicted five weeks previously, to the head of the third metacarpal bone of the right hand, which had been struck a severe blow against a metal oil-guard. Pain started at the time of the injury, and has persisted. It shoots down to the finger-tips. It is worse when he grips; there is none at night. Clinical examination revealed limitation of motion at the third metacarpophalangeal joint, and "wincing" tenderness at the head of the metacarpal. A roentgenogram revealed no fracture, but on close scrutiny a pea-sized cyst at the radial side of the head of the metacarpal and anteriorly.

Under nitrous oxid anesthesia and Esmarch anemia, an incision was made just to the radial side of the extensor tendon of the middle finger, and the bone was exposed by retracting the capsular ligament. The bone was removed from the proximal and radial portion of the head until the cyst was emptied. It was pea-sized and filled with clear, tenacious mucoid material. The cyst wall was curetted, phenolized and packed with iodoform gauze. The edges of the deep fascia were approximated. Hemostasis was secured and skin edges were approximated. A splint was applied. After the operation the patient stated that immediate relief from the shooting pain was afforded.

A roentgenogram, taken when the wound was entirely healed, shows the remains of the cyst cavity outlined by iodoform powder, which was inserted into it at a dressing a few days after operation. The cavity is much diminished in size.

A review of recent literature reveals but one case that may be compared with mine. McDill[1] reports a cyst in the distal half of the fifth metacarpal bone. It began three years previously as a small, painless swelling which gradually increased for a year, when it swelled rapidly, became painful, and was opened, giving exit to stringy mucopus, and discharged at intervals for the remaining two years. The roentgenogram shows an oval cyst with one end at the neck of the bone and the other just below the middle of the shaft, of which it occupies two-thirds of the width and one-fifth of the length. The shaft is not expanded. McDill says: "So far no case has been reported in the long bones of the hands or feet." Silver,[2] in a series of ninety-seven cases of bone cysts, found but one each in a metacarpal and metatarsal bone. Elmslie,[3] in an extensive review of the subject, says: "Most of the cysts of the metacarpal and metatarsal bones and of the phalanges have been definitely myxomatous, resulting from degeneration in enchondromata."

Robert Jones[4] describes three large cysts in the bones of the hand: expansion was present in all. Indeed, perusal of the literature of bone cysts shows that enlargement was almost invariably present. The cysts, colossal in comparison with mine, with the single exception of McDill's case, represent, without doubt, advanced stages of pathology. This, together with the fact that the whole subject of bone cysts is comparatively recent, forces me to the conclusion that my cases represent the earliest stage, the stage in which it is most desirable to recognize any disease. It must be borne in mind that there was no enlargement in either case; that in both there was the history of localized trauma, of persistent but not severe pain, and of localized but not typically "wincing" tenderness. In fact, there was the clinical picture of a "chipping" fracture with lingering signs, because untreated. It was only by close scrutiny of the skiagram in the first case for such a chip that the minute cyst was discovered. In the second case detection of the cyst was facilitated by the memory of the first case, which had preceded it by only three months.

As to the pathology, I am unable to present any observations. The cysts were so minute that it would have been unjustifiable to resect the bones in order to study the cysts. At operation, each cyst had a sharply defined globular wall, and the contents resembled the vitreous body of the eyeball. By correlation, however, I incline to the opinion that the cysts are the result of hemorrhagic osteomyelitis, which has been described by Barrie and Hillman,[5] who define it thus: "The term hemorrhagic osteomyelitis is meant to embrace a majority of those traumatic, localized, non-infective (so far as we know at present), non-suppurative, low-grade inflammatory lesions that have their onset in spongy bone." The slight trauma in my cases was sufficient to cause fractures of the delicate normal bone trabeculae, producing effusion, hemorrhage, and interference with nutrition, thereby setting up a localized osteomyelitis. The pigments of the blood were absorbed, leaving clear contents, just as occurs in cysts of soft tissues, notably in pancreatic cysts of hemorrhagic origin.

I have noticed several times minute cysts about the size of the head of a pin in the carpal semilunar in roentgenograms taken for other conditions, but doubt if they were true cysts. A study of trabeculae in roentgenograms shows that cysts may be simulated by certain arrangements of lights and shadows. The best way to avoid error is to correlate clinical findings with those of the roentgenogram.

CONCLUSIONS

1. Cysts of bone should be detected in their incipient stages before extensive destruction of the medulla has taken place.

2. Early operation results in prompt cure, and prevents deformities and extensive bone plastics.

3. A localized trauma followed by persistent but not severe pain, and localized but not true "wincing" tenderness—symptoms and signs of an untreated "chipping" fracture—should arouse clinical suspicion of a minute, early bone cyst, the corroboration of which may be afforded by close scrutiny of a roentgenogram at the site corresponding to that of the localized tenderness.

SUPRAPUBIC PROSTATECTOMY*

CHARLES E. BARNETT, M.D.
FT. WAYNE, IND.

On account of the mortalities occurring, no one is exactly satisfied with his technic in prostatectomy, except for the present time, but naturally he thinks that just now it cannot be improved on.

The men who do the greatest number of operations do not necessarily have the best technic for general use, for that which is easy for the one who knows how may be impossible for the other man. Then, too, the operator before a clinic may devise an operation for "sight seeing" for the spectators that will aggrandize himself at the expense of the patient.

Gentleness, thoroughness with simplicity is becoming the more fashionable prostatectomy. The time is also present when an operator is more easily divorced from a false opinion than heretofore.

Prostatectomy seems to have reached the stage where the lesser points are deemed essential.

There are possibly four principal reasons for the suprapubic operation to carry the greatest preference at the present time:

1. The danger of the pus-bathed perineal tube forcing infection into the torn open-mouthed veins and thereby producing emboli and thrombi.

2. The greater ease of local anesthesia in the suprapubic region.

3. The avoidance of trauma through the pelvic diaphragm.

4. The comparative ease and simplicity of postoperative treatment.

From the results following non-irrigation for the control of hemorrhage, it would seem that irrigation was a menace rather than a benefit, especially when the preoperative preparation endeavors to improve the fibrin product of the blood. The clot formed in the bladder assists in checking further hemorrhage. Irrigations were necessary only during times past when the drainage-tube lumen was small.

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

For the same reason that a perineal drainage-tube carries a possible danger of forcing pus into the torn open-mouthed veins, so also is a retained urethral catheter contra-indicated. The fact is that even sounding of the urethral canal is quite hazardous as a late postoperative procedure for fear pus will be forced back through the ejaculatory ducts or out of the vas ampulla to infect the epididymis.

The lack of shock is so marked following operation under local anesthesia that it would seem advisable to operate under local anesthesia in all cases to the farthest degree whereby pain is not felt by the patient, supplementing finally general anesthesia, if necessary, until the prostate is removed, then fixing the drain and closing the wound under the retained local anesthesia.

The most perfect postoperative recovery which I have ever experienced occurred in the following case:

Mr. S., aged 76, Feb. 2, 1914, No. 250-S. The man was young for his age. Following a perfect preoperative preparation the patient was operated on under local anesthesia. The skin from just below the umbilicus to pubes and also the deep linea alba were injected with 1 per cent. cocain solution. All fascial and muscular planes laterally were injected with 1:400 novocain, as well as the bladder wall. After opening the bladder (incision extending 1 inch pubically from peritoneal fold) the prostate was injected deeply with 1 per cent. cocain while the pericapsular region was injected with the 1:400 novocain solution. The operation was painless, except for a short period during the prostatic enucleation. A 1-inch drain was purse-stringed into the roof of the bladder; small cigaret drain to Retzius' space; wound was closed without additional local anesthetic. Patient was put to bed without the Fowler elevation, attended by a special nurse, without irrigation for hemorrhage. The only inconvenience in the convalescence, which by the way was not experienced by the patient, was gas collections in the ascending and transverse colon.

At the Los Angeles session, several years ago, I spoke of the importance of chronic colitis playing an important influence in prostatectomized patients. I still think that the subject does not receive the general attention that it deserves. Old prostatics generally have indolent constipated bowels, which are much influenced by the renal toxemia which has induced, from the years of pathology, a chronic inflammation of the colon. This colic pathology is aggravated by and itself superinduces gas distention which opens up another field for toxic absorption, which added to the overloaded kidneys adds another weight toward dissolution.

The toxemia from the distended colon, even when the kidneys show a fairly quantitative and qualitative urine, is so profound that the temperament of the patient will become so disagreeable, so changed, that the nurses' patience will be tried sometimes to the point of breaking.

I have noted flights of temper in these patients which were entirely unnatural and unnecessary. While the distention was giving the patient no discomfort from pain, yet, just as soon as the distention was relieved, the temperature and temperament of the patient returned to norm[illegible] place of the principal thoughts of the surgeon shoul[illegible] tend to preparatory treatment to correct and in the [illegible] ve treatment to remove the gas distention o[illegible]

THE ULTIMATE RESULTS OF GENITAL TUBERCULOSIS IN THE MALE*

J. DELLINGER BARNEY, M.D.
Genito-Urinary Surgeon to Outpatients, Massachusetts General Hospital; Assistant in Genito-Urinary Surgery at the Harvard Medical School
BOSTON

Genital tuberculosis in the male is a very grave affection. It does not indicate, as many suppose, an infection of the genital tract alone. On the other hand, a careful analysis of many cases shows it to be merely another outbreak of a tuberculous infection which has been smoldering sometimes for years.

In an analysis of 153 cases of epididymal tuberculosis seen at the Massachusetts General Hospital, I[1] found evidence of tuberculosis of other organs, notably lungs, in 35 per cent. In most of these (29 per cent.) the disease was active at the time of entrance to the hospital. In the present series of cases, 154 in all, tuberculosis of organs other than those of the genital tract was found to exist in 55.8 per cent., the lung again being most frequently involved with a total of thirty-five cases, 22.7 per cent. of the whole. Kidney and bone infections came next with seven cases each. Genital tuberculosis is, therefore, to be regarded as but another manifestation of an active tuberculous infection and a lowered resistance on the part of the patient.

Tuberculosis of the genital tract affects the epididymis primarily. So far as I am aware, no case starting elsewhere than in the epididymis has been observed in a now considerable experience; nor, so far as I know, do the records of the Massachusetts General Hospital contain such an instance. Guisy,[2] in 183 cases of genital tuberculosis, found but ten involving the prostate and vesicles alone; while Saxtorph[3] observed only nine in a series of 205 similar cases. Infection starting elsewhere than in the epididymis is, therefore, exceedingly uncommon. In the urinary tract the primary focus is always in the kidney, a fact borne out by ample clinical and pathologic experience.

The general profession is too apt to use loosely the term "genito-urinary tuberculosis." While the genital and urinary organs may each be tuberculous, careful inquiry will show infection of the one tract to be secondary to that of the other. An analysis of the 154 cases now under consideration has shown a tuberculous infection of the kidney in eighteen. Of these, the genital lesion preceded the renal infection in eleven, whereas in seven the kidney was first involved. In one or two other cases, observed by me, but not included here, the latter sequence has also occurred. It is thus seen that the infection extends more often upward than downward, a fact which in my opinion favors strongly the transmission of the tubercle bacillus by the lymphatic route. In those cases in which epididymal tuberculosis of one side is followed by an involvement of the opposite kidney it is to be accounted for by a crossing of the lymphatics at the base of the bladder. If such infection took place by way of the blood-stream it seems reasonable to suppose that the kidney would more often be the primary focus of the genito-urinary tract. On the other hand, one might argue that a greater resistance of the kidney to the onslaught of the tubercle bacillus was the determining factor in the order of events.

Let us now see what encouragement can be held out to the patient with tuberculosis of the epididymis. Of 154 cases taken from the records of the Massachusetts General Hospital, 113 have been traced since operation. Of these, 31 patients are known to have died of tuberculosis. Eight more have died of other causes, but it seems highly probable that a majority of these were still tuberculous at the time of their death. Sixty are now living. I have personally examined 32 of these men anywhere from two to fifteen years after operation. By letter and otherwise, satisfactory statements of bodily health have been obtained in 28 others now living at from two to twenty-six years after operation. Information as to 13 more, living from one to three years after operation, but since lost sight of, is also included because of certain important facts.

The old saying, "There is no Indian like a dead Indian" is peculiarly applicable to the individual infected with tuberculosis. When we say that until he is dead he is apt to break out with some new manifestation of the disease we are not far from the truth. Four died, in the hospital, within a month after operation, all of miliary tuberculosis, 3 of them so proven by necropsy, giving a figure for the 28, of the 31 whose postoperative length of life is known, of 14.2 per cent. Within the first six months after operation (including the 4 mentioned above) 9, or 32.1 per cent. died, whereas a total of 14, or 50 per cent., succumbed within the first year. From this point, until the end of the sixth year, the death-roll drops rapidly, but we find that during the first six years after operation, 85 per cent. have died. Thus although we see that half of these unfortunates were gathered in by the end of the first year, and over three-quarters of them by the end of the sixth year, it is important to find that 3, or 10.7 per cent. died of tuberculosis between the ninth and eleventh years, a fact which warrants the belief that until at least ten years have elapsed after operation, no patient can be said to be cured. The facts here presented are somewhat different from those of other writers. Lapeyre[4] says that 75 per cent. of these patients are cured, and that a survival of the patients of from four to ten years after operation is to be expected. Brunt and Brungner[5] reported 56 per cent. of favorable remote results, while Haas[6] speaks of 45 per cent. of permanent cures. In my opinion these figures are misleading for the reason that the patients have not been followed over a sufficient number of years. Taking my own cases for a period of six years after operation I find that in a total of 58, of whom I know the definite results, 24, or 41 per cent., have died of tuberculosis.

An analysis of the particular manner in which the tubercle bacillus gave its death blow is illuminating. In 7, or 22.5 per cent., a general miliary process closed the scene, while in an equal number renal tuberculosis was the determining factor. Lung involvement came next in order with a percentage of 16.1 per cent. The cause of death in 10 others was given simply as "tuberculosis" without reference to the organs involved, while "meningitis" and "fistula in ano" each claimed one victim. That these 31 dying of tuberculosis were already doomed seems clear when we see how extensive was the involvement, either in the past or at time of operation, of organs other than those of the genital tract. In 15 (practically 50 per cent.) the lungs were already involved at time of entrance to the hospital, kidney and bone infections coming next in order with 4 cases each. Other tissues and organs such as larynx, joints, meninges, glands and middle ear each contributed their quota. Yet none of these cases, in spite of evidences of tuberculosis elsewhere, was considered by the surgeon as a bad risk.

Of the group now known to be living at periods of from two to twenty-six years after operation (sixty in all), the lungs were affected only 8 times, kidney 3 times, and other organs once or twice each. Among the thirteen heard from within the first year or two after operation, but trace of whom has since been lost, lung tuberculosis was found in three instances.

The extent of the genital lesions of the living and of the dead was about the same. In most a single epididymal infection was found, while the prostate and seminal vesicles were involved in about the same proportion of cases in all groups.

The urines of those now dead contained pus, blood, albumin and casts in various combinations in 77 per cent., while of the patients living the urine was pathologic in but 38 per cent.

The guinea-pig test of the bladder urine in these cases has been sadly neglected both before and after operation. Yet it is a point of the utmost importance, not only for purposes of diagnosis, but also of prognosis. If a positive test is obtained, it shows either that there is renal involvement, or that the bladder has become infected by way of the prostate. Even with the urine free from tubercle bacilli we may find it to contain pus, blood and albumin. These elements, in the presence of marked bladder irritability, may well lead us to suspect tuberculosis of the kidney, and if this exists that organ must be first dealt with. In eight out of ten of this series tubercle bacilli were found in the urine before operation. In six patients now living and seen by me, guinea-pigs have been inoculated with the bladder urine. Four, formerly negative, have since developed tuberculous kidneys and give a positive test. One patient whose kidney was removed for tuberculosis six years before the genital lesion developed now has a urine free from tubercle bacilli. Four other cases are likewise negative, and were so before operation. One of these has since had a relapse in the second epididymis.

Seventeen of the 32 patients seen by me have had a fresh outbreak of tuberculosis since the removal of their first epididymis. In 4 the second epididymis has become involved, while in 4 others kidney tuberculosis (bilateral in one case) has intervened. Three patients have developed ischiorectal abscesses with a persistent fistula in ano, 2 are now suffering from disease of the bone (one of the hip, one of the spine) and 1 case each of phthisis, corneal ulcer, glandular tuberculosis and funiculitis has been seen. In other words, the fire has not yet burned itself out.

Of the 31 who died of tuberculosis, 15 developed tuberculous foci after operation elsewhere than in the genital tract, and succumbed later to additional and more extensive exacerbations of the disease. Thirteen of the 32 patients seen by me have thus far presented a clean score except for the epididymal infection. In most instances they have gained weight and seem to be in perfect health. The remainder are or have been handicapped, as described above, by other manifestations of the disease. I have observed elsewhere[7] that azoospermia obtains in tuberculosis of the epididymis (even when unilateral) in 85 per cent. Further observations confirm this statement. I also remarked that the lesion in question did not disturb the sex function. This conclusion is also still sound. Even after double orchidectomy the adult seems to be unaffected as regards his masculinity. Two of our patients, so handicapped, asserted that they were perfectly normal from a sex point of view in regard to both desire and ability to perform the sexual act.

[4] Lapeyre: Arch. gén. de Chir., July, 1912, No. 7.
[5] Brunt and Brungner: German Cong. of Surgeons, 1901.
[6] Haas: Beitr. z. klin. Chir., 1901, xxx.

We now have the records of nearly 100 epididymectomies at the Massachusetts General Hospital. I have remarked elsewhere[8] that not one of these patients has yet been obliged to submit to a subsequent orchidectomy. This statement still holds true in spite of the fact that the testicle, in our experience, is clinically tuberculous in 44 per cent. of cases, and microscopically so, in cases of orchidectomy, in 66 per cent. In other words, where experience and judgment are exercised, the testicle need rarely be removed with the epididymis.

In sixty-nine of the patients analyzed here the prostate and seminal vesicles were found to be tuberculous at the time of entrance to the hospital. Many of those now living have since been examined by me at various intervals of time after operation. In most instances the induration, nodularity and tenderness of the prostate and vesicles, present before operation, has subsequently disappeared entirely, or decreased in extent. In a few the condition is the same as before operation. In two instances the process continued after operation, and formed an abscess which opened spontaneously, or was drained, with the establishment of a permanent perineal fistula, from which urine has leaked at times. This experience, although brief and incomplete, substantiates the belief which I have always held, namely, that the prostates (including seminal vesicles) which are markedly tuberculous had best be left alone, and, like those which are only slightly or moderately infected, will generally take care of themselves after removal of one or both epididymes. I regard attempts at complete excision of the tuberculous prostate and seminal vesicles as not only useless but impossible.

A broad view of the whole subect of surgical tuberculosis, and of genital tuberculosis in particular, demonstrates beyond question that, taken all in all, the odds are against the patient. The longer he can live and fight down any particular outburst of the disease the better able he is, in most instances, to overcome the next exacerbation. It all comes down to a question of immunity. Once fortified in this manner a patient can ward off an onslaught of the tubercle bacillus, which, under other circumstances, would get the upper hand in a short time. While we have all seen patients with surgical tuberculosis, who have fought single handed a winning battle for many years, we should not hesitate to bring to their relief the best of hygienic treatment, the regular and continuous administration of sandalwood oil, and the use of tuberculin. The latter should be given only after operation, must be given cautiously and intelligently, and should be employed for an almost indefinite time. Under these conditions whatever natural immunity the patient may possess, or has acquired, will be raised to the highest possible point, a factor which I believe will give the victims of this disease a better outlook in the future than they have had in the past.

SUMMARY

1. Tuberculosis of the genital tract is accompanied by old or active lesions in other organs in more than 55 per cent. of cases, most of them being in the lung.

2. The genital tract is usually first attacked in cases of genito-urinary tuberculosis.

3. Over 27 per cent. of 113 patients traced have died of some form of tuberculosis. Within a period of six years after operation 41 per cent. of 58 patients have died of this disease. Of the deaths from tuberculosis, 14.2 per cent. occurred within one month, 32.1 per cent. within six months and 50 per cent. within one year after operation. During the first six years 85 per cent. died, while between the ninth and eleventh years 10.7 per cent. succumbed. Miliary, renal and lung tuberculosis are, in order, the final types of the disease. A large majority of those dying of tuberculosis had had one or more outbreaks of the disease both before and after operation. My experience warrants the conclusion that until at least ten years have elapsed after operation, no patient can be said to be cured of tuberculosis.

4. The records of those now living show a much smaller percentage than do those of the dead, of other tuberculous processes before operation, but many of them have since developed other foci. As 81 per cent. of those examined and 28.5 per cent. of those corresponded with are still within the six-year period, in which I found that 85 per cent. of deaths had occurred, it is to be expected that the deaths in this group, *from* tuberculosis, are not yet at an end.

5. While genital tuberculosis, even if unilateral, results in sterility in most cases, neither the disease nor the operation for its relief, including double orchidectomy, seems to impair masculinity in any way.

6. In none of my cases of epididymectomy has the patient returned for a subsequent orchidectomy, although in three instances (one has already been mentioned) there has occurred a tuberculous funiculitis, simulating testicular involvement.

7. My experience has shown that although the prostate and seminal vesicles are involved in most cases of epididymal tuberculosis, their condition will improve or heal after removal of the epididymis. Radical surgical treatment of these organs is unnecessary and unwise.

8. The long life and good general condition of many of my patients, even although suffering from repeated outbreaks of tuberculosis, shows that the survival of the patient depends largely on his ability to immunize himself to the disease. Therefore our efforts must be directed, not merely toward suitable surgical treatment, but also toward helping him develop that immunity which is so important. For this purpose hygiene, sandalwood oil and tuberculin are essential.

374 Marlboro Street.

ABSTRACT OF DISCUSSION

Dr. B. C. Corbus, Chicago: I am particularly interested in the point that Dr. Barney makes with reference to establishing an immunity in these cases. During the last two years I have been interested in the work of Dr. Karl von Ruck of Asheville, N. C., with regard to the immunization of children and adults in general tuberculosis, and have recently done some work in his laboratory. I came to realize the possibility of immunization before surgical interference is attempted. We all realize how necessary it is to put our patients in the best possible condition to withstand any kind of a surgical operation, no matter what the infection may be, but most surgeons apparently desire to operate as soon as possible in a case of surgical tuberculosis. That it is absolutely necessary to remove every caseous focus that exists, is granted. In immunization before operation, the idea is to use a vaccine that contains all the particles of the tubercle bacillus in proper proportion, a vaccine that will stimulate the formation of antibodies in every part, the patient's serum being tested for these antibodies before operation, so that one can demonstrate whether the patient has a specific resistance. This seems to me to offer more advantage than an immunization afterward.

---

[8] Barney, J. Dellinger: Boston Med. and Surg. Jour., 1913, clxviii, No. 25.

Dr. Robert H. Herbst, Chicago: I agree with Dr. Barney that if not in all, in most cases of genital tuberculosis we find the process beginning in the epididymis. The reason for this is obvious if we stop to consider that in the epididymis we find small tortuous blood-vessels on the walls of which the tubercle bacillus readily implants and forms a focus of infection. From a therapeutic point of view I think that it is well to divide cases of genital tuberculosis into two classes: first, those in which the process is limited to the epididymis; secondly, those in which we have to deal with an involvement of the cord, prostate and seminal vesicles. In the first class epididymectomy or orchidectomy with removal of a part of the cord will, as a rule, be followed by good results. In the second class, however, in which the process has extended to the lower end of the genital tract, the patient is far better off without surgery and instead should be relegated to tuberculin treatment with the usual hygiene for tuberculosis.

Dr. J. H. Cunningham, Jr., Boston: I have recently looked up the necropsy records of the Boston City Hospital in cases recorded as tuberculous epididymitis. In twenty such cases a microscopic examination was made of the prostate and seminal vesicles. It is interesting to note that, out of these twenty cases, in eleven the disease was bilateral in the epididymis, and in nine it was unilateral. Of these twenty cases the prostate was involved in eleven; the seminal vesicle also in eleven. When the vesicle was involved the prostate was also involved in each instance. Of the eleven bilateral cases of tuberculous epididymitis, involvement of the seminal vesicle was bilateral in seven and unilateral in four. Of the twenty cases the testicle was involved in only four. In two of the cases involving the epididymis, vesicles and prostate the lesion in the epididymis was caseous, suggesting primary tuberculosis in the epididymis, there being an acute miliary infection of all the visceral organs in these two instances. There are unquestionably cases of tuberculous epididymitis in which it is impossible clinically to detect tuberculosis in the prostate or seminal vesicle even when it is there, and the successful dealing with the condition within the scrotum by surgical measures, allows the disease in the prostate and vesicle to remain quiescent or at least not to progress to the point of producing symptoms in most instances. Especially is this true if these patients receive tuberculin and carry out the hygienic measures which have been proved to be beneficial in controlling tuberculosis wherever located. This postoperative treatment is most important after the primary focus is removed, because clinically, as in these twenty cases in which necropsy has been performed, we have found that the majority of the patients with tuberculous epididymitis have associated tuberculosis in the vesicles, prostate or elsewhere in the body.

Dr. E. L. Keyes, Jr., New York: I have seen but one case of relapse of tuberculosis in the testis after removal of the epididymis. The patient had had one epididymis removed for tuberculosis two years before. At that time he had a tuberculous ischiorectal abscess and fistula which were not touched. The scrotum healed after the removal of the epididymis, the testicle being left in, but broke open six months later. He returned to the hospital, with an extension of the process around the rectum, involvement of the opposite epididymis and a relapse in the testicle which had been left behind after the removal of the epididymis. I agree with Dr. Barney that the testicle can always be saved when it is mechanically possible to remove the epididymis and still leave the testicle some blood-supply, but I wish to report this single instance of recurrence after apparent healing subsequent to epididymectomy.

Dr. J. D. Barney, Boston: I understood Dr. Herbst to say that in cases in which the prostate and vesicles were involved, surgery had better not be done. We have found in a previous analysis of a great many cases that in 75 per cent. the prostate and seminal vesicles are involved, and I made the remark then that probably a great many more were involved that we could not detect because it is possible in the vesicle and prostate to get early foci which cannot be felt with the finger. I think 75 per cent. is conservative. If one goes on the basis of these figures and if one adopts Dr. Herbst's belief it leaves a very small percentage that can be operated on. I have shown the results in a great many cases in which the prostate and vesicles were distinctly involved before operation and in which they are now so nearly healed that it is very hard to detect any tuberculous foci in them. That, it seems to me, is the answer to this objection.

OBSERVATIONS OF THE RESULTS OF SEVEN MONTHS' EXPERIENCE WITH SALVARSAN IN THE TREATMENT OF SYPHILIS

KENT NELSON, M.D.
Surgeon, United States Military Prison
AND
EDGAR F. HAINES, M.D.
Assistant Surgeon, United States Military Prison
FORT LEAVENWORTH, KAN.

In March, 1914, we published[1] the results of our observations with neosalvarsan in the treatment of syphilis. This report showed that after five intravenous injections of neosalvarsan combined with intensive mercurial treatment, the Wassermann reaction had become negative in 33.3 per cent. and remained positive in 66.7 per cent. of the cases treated. These results were considered so poor that it was believed a further use of neosalvarsan at this institution was not warranted. Since Jan. 10, 1914, salvarsan has been substituted for neosalvarsan, and the results of that substitution are here recorded.

Seventy-four cases of syphilis have been treated at the Prison Hospital during the past seven months. Twenty-five of these cases have been selected for report in this paper. These twenty-five cases have received their entire treatment at the Prison Hospital, and the original and all subsequent serum tests have been performed by the same medical officer (Capt. Charles Craig, Medical Corps, U. S. Army). In the remaining forty-nine cases the treatment was started elsewhere, the original Wassermann test having been made by other medical officers; in short, the treatment of these cases was simply continued at this institution.

Each patient here reported has received four intravenous injections of 0.6 gm. of salvarsan and twelve intramuscular injections of 100 mg. of the salicylate of mercury. The salvarsan has been given at ten-day intervals, the mercury, two injections a week. No bad effects from the intramuscular injections of the mercury have been noted. The prisoners here are all engaged in active outdoor work, and state that they have felt no discomfort in the muscles following injections. The intravenous puncture has been employed in each administration of salvarsan.

---

[1] Nelson, Kent, and Haines, E. F.: Observations of the Results of Nine Months' Experience with Neosalvarsan at the United States Military Prison Hospital, Fort Leavenworth, Kan., The Journal A. M. A., March 28, 1914, p. 989.

Table 1 shows that no reaction followed the administration of salvarsan regardless of the stage of the disease. It has been stated by some that there are a greater number of reactions following the use of salvarsan than when neosalvarsan is used. The cases treated at this hospital do not bear out this statement. We consider all cases severe in which the temperature is above 102 F., with or without other symptoms; moderate, when the temperature ranges from 100 F. to 102 F.; mild, normal temperature to 100 F. Cases are deemed as having no reaction when there are no high temperature and no symptoms.

TABLE 1.—REACTIONS ACCORDING TO THE STAGE OF DISEASE

Stage of Disease	Number of Cases	Total Number of Injections	Reactions Severe	Moderate	Mild	None	Percentage of Negative Reactions
Primary	1	4	0	0	0	4	100
Secondary ..	17	68	0	0	0	68	100
Tertiary	1	4	0	0	0	4	100
Latent	6	24	0	0	0	24	100
Total	25	100	0	0	0	100	100*

* Average negative.

An analysis of Table 2 shows that 64 per cent. of the cases here reported have become negative and 36 per cent. remained positive. Our report on neosalvarsan showed that after each patient had received five intravenous injections, combined with intensive mercurial treatment, 33.3 per cent. became negative, and 66.7 per cent. remained positive. In other words, with salvarsan we have obtained nearly twice as many negative reactions as with neosalvarsan, 64 per cent. of the cases becoming negative against 33.3 per cent. with neosalvarsan. Five intravenous injections of neosalvarsan were used, where only four of salvarsan were given. It was stated in our report on neosalvarsan that the results of our work with that drug did not seem to warrant the belief that neosalvarsan should be given in the proportion of 3 to 2 of salvarsan, but that it should be given either 6 or 8 to 2. The results that have now been obtained with salvarsan seem to prove this statement, for four injections of salvarsan have given nearly twice as many negative Wassermann reactions as did five injections of neosalvarsan.

TABLE 2.—THE RESULTS OF TREATMENT WITH SALVARSAN ON THE COMPLEMENT-FIXATION TEST IN THE VARIOUS STAGES OF SYPHILIS

Stage of Disease	Total Cases	Became Negative No.	Per Cent.	Remained Positive No.	Per Cent.
Primary	1	1	100	0	0
Secondary	17	12	70.7	5	29.3
Tertiary	1	0	0	1	100
Latent	6	3	50	3	50
Total	25	16	64	9	36

Repeated Wassermann tests have been made in all the cases here reported, all by the same medical officer (Capt. Charles Craig) who likewise made all of the serum tests of the cases reported in our work on neosalvarsan. We have thus secured an absolute uniformity of technic and interpretation of the serum reactions, thus giving accurate data regarding the results of our treatment as indicated by the Wassermann reaction.

Table 3 shows that out of 16 cases that became negative, 5 were during the first month, 9 were negative by the second month, 13 by the third month, and 15 at the end of the fourth month. In other words, 15 of the 16 negative results were obtained by the end of the fourth month. In our report on observations with neosalvarsan, a similar table to Table 3 of this paper showed that out of 68 cases 23 became negative. One the first month, 1 the second, none the third, 3 the fourth, 3 the fifth, 4 the sixth, etc. In other words, at the end of four months, 5 of our cases out of a total of 23 negative had shown a negative reaction; or, more briefly stated, with neosalvarsan 21 + per cent. of our negative cases showed the negative reaction within four months, whereas with salvarsan 93 + per cent. of the negative cases showed the negative reaction within four months. This demonstrates very clearly the rapidity of action of the two drugs.

TABLE 3.—RELATION OF THE STAGE OF SYPHILIS TO THE TIME OF DISAPPEARANCE OF COMPLEMENT FIXATION AFTER TREATMENT WITH SALVARSAN

Stage of Disease	Total Cases	Month 1st	2d	3d	4th	5th	6th	7th	Total Negative
Primary	1	..	..	..	1	..	..	..	1
Secondary	17	4	3	3	1	..	..	1	12
Tertiary	1	..	..	..	..	..	..	..	..

TABLE 4.—RELATION OF THE INTENSITY OF THE COMPLEMENT FIXATION TO THE DISAPPEARANCE OF THE REACTION AFTER TREATMENT WITH SALVARSAN

Character of Reaction *	Total Cases	Became Negative No.	Per Cent.	Remained Positive No.	Per Cent.
++	14	6	42.8	8	57.2
+	6	6	100	0	0
+—	5	4	80	1	20
Total....	25	16	64	9	36

* A ++ reaction represents an absolute inhibition; a + reaction, any degree between 75 per cent. and absolute inhibition; a + —, any degree between 50 per cent. and absolute hemolysis.

A study of Table 4 shows that the stronger the serum reaction, the fewer cases that became negative. With a ++ reaction 42.8 per cent. became negative, with a + reaction 100 per cent., and with a +— 80 per cent. These results do not differ in any material way from those obtained by us with neosalvarsan.

Table 5 shows that in the 6 negative ++ cases all of the negative reactions were obtained by the end of the fourth month; that all of the + cases were negative by the end of the third month; and 3 out of the 4 negative +— cases were negative by the end of the second month. In our report on neosalvarsan 40 ++ cases were recorded, 13 became negative, but

TABLE 5.—RELATION OF THE INTENSITY OF THE COMPLEMENT FIXATION TO THE TIME OF DISAPPEARANCE OF THE REACTION AFTER TREATMENT WITH SALVARSAN

Character of Reaction	Total Cases	Month 1st	2d	3d	4th	5th	6th	7th	Total
++	14	1	1	2	2	..	..	..	6
+	6	2	2	2	..	..	..	..	6
+—	5	2	1	..	..	..	..	1	4
Total......	25	5	4	4	2	0	0	1	16

at the end of the fourth month only 2 of the 13 had shown the negative reaction. Nineteen + cases were reported, 6 of which became negative, 2 showing the negative reaction at the end of the fourth month. Nine +— cases were recorded; 4 became negative, only one of which showed a negative reaction by the end of the fourth month. A study of Table 5 shows clearly as does Table 4 the more rapid action of salvarsan.

CONCLUSIONS

1. Four injections of salvarsan combined with intensive mercurial treatment have given nearly twice as many negative serum reactions as did five injections of neosalvarsan with mercurial treatment.
2. The best authorities state that with our present methods of treating syphilis we cannot expect to obtain over 70 or 80 per cent. of negative Wassermann reactions. Salvarsan has given us 64 per cent. of negative serum reactions, whereas neosalvarsan gave 33.3 per cent. in nine months.
3. The drug should be used which will bring about the best results in the shortest possible time. We believe that our work with neosalvarsan and salvarsan will clearly demonstrate that salvarsan is the drug.
4. A greater number of reactions should not follow the use of salvarsan.
5. The complement fixation is of the greatest value in diagnosis, or as an indicator to the results of treatment.
6. We believe that the results reported in this paper are of such a character as not to warrant the further use of neosalvarsan in the military service; and to all others who desire to give their patients the best possible results in the shortest possible time.

FACTORS GOVERNING VASCULAR DILATATION AND SLOWING OF THE BLOOD-STREAM IN INFLAMMATION *

PAUL G. WOOLLEY, M.D.
CINCINNATI

Inflammation is a process characterized by symptoms which have been referred, directly and indirectly, to changes in caliber of blood-vessels, and to other less definite changes which are grouped under the term "changes in permeability" of vessel-walls. The changes in caliber have been used in explanation of the increased redness and of the apparent increase in temperature of an inflamed area. The phenomena of exudation, including emigration and diapedesis, have been referred to "changes in permeability." These latter phenomena always follow the former.

Vascular dilatation is a normal, physiologic process by which the blood-supply of an organ is increased during physiologic activity. It is an adaptive mechanism. It occurs under any circumstances which bring about increased metabolic activity, and appears under all sorts of conditions which are unassociated with the symptoms or morphology of inflammation. Nevertheless, it is a fundamental phenomenon of the inflammatory process; therefore, in discussing that process, it is necessary to offer an explanation of vascular dilatation.
